covered with water, or the soil is extremely wet, they may be drained, as large districts in the fens of Lincolnshire have been, and made highly valuable. The object, in that case, is, by embankments, draining, and other means of improvement, to convert these marshes into pasture or meadow, or even arable lands; and where such improvements cannot be accomplished, the most useful woody aquatics, as willows, osiers, &c., may be grown with advantage.

4559. Romney marsh is one of the most extensive and fertile fresh-water marshes in Britain. It contains nearly 24,000 acres; besides which Walland marsh and Dinge marsh, which are comprised within the walls, contain, the former 12,000, and the latter 8,000 acres. Boys informs us that "the internal regulations of these marshes are committed to the superintendence of expenditors. These are appointed by the Commissioners of Sewers, and are to take care that the repairs of the walls are maintained in due order, and that the costs attending the same be levied on each tenant according to the number of acres occupied by him; for which purpose they are to cause assessments to be made out, with the names of the occupiers, and the rateable proportions to be borne by them respectively; and these rates, which must be confirmed by the commissioners, are termed scots; and that when any occupier refuses to pay his scot, the expenditors can obtain a warrant from the commissioners, empowering them to distrain for the same, as for any other tax." These marshes are both appropriated to the purposes of breeding and feeding.

4560. Salt water marshes are subject to be overflowed at every spring tide, and at other times, when, from the violence of the wind or the impetuosity of the tide, the water flows beyond its usual limits. Their goodness is in a great measure analogous to the fertility of the adjoining marshes; and their extent differs according to the situation. Embankments, as it is remarked in The Code of Agriculture, are perhaps the only means by which they can be effectually improved, especially when they are deficient in pasture. However, where pasture abounds, they are in some cases more valuable than arable lands, the pasture operating as a medicine upon diseased cattle.

4561. Marshes on the Thames. In The Agricultural Survey of Kent it is asserted, that great profit is made by the renters of marshes bordering on the Thames, in the neighbourhood of London, from the grazing of horses, the pasture being deservedly accounted salubrious to that useful animal. Such horses as have been worn down by hard travel, or long afflicted with the farcy, lameness, &c., have frequently been restored to their pristine health and vigour, by a few months' run in the marshes, especially on the saltings; but as every piece of marsh land in some measure participates of this saline disposition, so do they all of them possess, in a comparative degree, the virtues above mentioned, and for this reason the Londoners are happy to procure a run for their horses, at 4s. or 5s. per week. Another method practised by the graziers in the vicinity of London is, to purchase sheep or bullocks in Smithfield at a hanging market, which, being turned into the marshes, in the lapse of a few weeks are not only much improved in flesh, but go off at a time when the markets, being less crowded, have considerably advanced in price; and thus a twofold gain is made from this traffic. Many of the wealthy butchers of the metropolis are possessed of a tract of this marsh land, and, having from their constant attendance at Smithfield, a perfect knowledge of the rise and fall in the markets, they are consequently enabled to judge with certainty when will be the proper time to buy in their stock, and at what period to dispose of them.

4562. In various districts of the island situated on the borders of the sea, or near the mouths of large rivers, there are many very extensive tracts of this description of land, which by proper drainage and enclosure may be rendered highly valuable and productive. This is particularly the case in Somersetshire and Lincolnshire. In the former of these counties, vast improvements have, according to Billingsley, as stated in his able Survey, been effected by the cutting of ditches, for the purpose of dividing the property, and the deepening of the general outlets to discharge the superfluous water. Many thousand acres which were formerly overflowed for months together, and consequently of little or no value, are now become fine grazing and dairy lands.

Sect. VII. Downs and other Shore Lands.

4563. Downs are those undulating smooth surfaces covered with close and fine turf, met with in some districts on the sea-shore; the soil is sometimes sandy, and at other times clay or loam. In inland situations there are also down lands, as in Wiltshire, Lincolnshire, and Yorkshire; in the latter two counties they are called wolds.

4564. Sandy downs on the sea-shore are often more valuable in their natural state than after cultivation. In a state of nature they frequently afford good pasture for sheep and rabbits, and at other times produce grasses that may be used as food for cattle, or as litter. But the great object should be to raise plants which contribute to fix these soils, and to prevent them from being drifted by the winds, which often occasion incalculable
mischief. The most suitable plants for the purpose are, the Elymus arenarius, Juncus arenarius, Arundo Donax, Oenonis spinosa, Galium verum, Tussilago Patasles, and a variety of other creeping-rooted plants and grasses. Of woody plants, the elder is one of the best for resisting the sea breeze, and requires only to be inserted in the sand in large truncheons. Where the sands on sea-shores are mixed with shells, and not very liable to drift, if they can be sheltered by fences or an embankment, and sown with white clover, it will be found both an economical and profitable improvement.

4563. The drift-sands of the outer Hebrides have in some places been consolidated and covered with verdure by 4 square pieces of turf, cut from solid sward, and laid upon the drifting surface, in steep places nearer to each other, and in less inclined places at a greater distance: on very rapid declivities the turfs are placed in contiguity. These turfs, although separated by intervals of a foot or so of sand, are not liable to be buried, except in very exposed places." (Quar. Journ. Agr., vol. i. p. 215.) N. Macleod, Esq. of Harris, has reclaimed and brought into useful permanent pasture above 120 acres of useless drifting sand, by planting it with Arundo arenaria (fig. 710). In 1819. The operation is performed in September, by cutting the plants about two inches below the surface with a small thin-edged spade, with a short handle, which a man can use in his right hand, at the same time taking hold of the grass with his left; other persons carrying it to the blowing-sand to be planted in a hole, or rather a cut, made in the sand, about eight or nine inches deep, (and deeper where the sand is very open and much exposed,) by a large narrow-pointed spade. A handful of Arundo arenaria, or bent grass, was put into each of these cuts, which were about twelve inches distant, more or less, according to the exposure of the situation. When properly fixed in the blowing-sand, the roots begin to grow and spread under the surface, in the course of a month after planting. This grass is relished by cattle in summer, but it is of greater value, by preserving it on the ground for wintering cattle: it would be injudicious to cut it, because it will stand the winter better than any other grass, and is seldom covered with snow. Neither wind, rain, nor frost will destroy it; but the old grass naturally decays towards the latter end of spring and the beginning of summer, as the new crop grows. White and red clover will grow spontaneously among this grass in the course of a few years, provided it is well secured. (Trans. Bnt. Agr. Soc. vol. vi. p. 203.)

4566. Poor sandy soils in inland districts are not unfruitfully stocked with rabbits. When the productions of arable lands are high, it is found worth while to break up these warrens and cultivate corn and turnips; but it frequently happens that, taking the requisite outlay of capital, and the expenses and risk into consideration, they do not pay so well as when stocked with rabbits. Such

warrens and cultivate corn and turnips; but it frequently happens that, taking the requisite outlay of capital, and the expenses and risk into consideration, they do not pay so well as when stocked with rabbits. Such

4567. Shores and sea beaches of gravel and shingle, without either soil or vegetation, are perhaps the most unimprovable spots of any; but something may be done with them by burying the roots of the arenarius grasses along with a little clay or loamy earth. Of these, the best is the Arundo arenaria and Elymus arenarius (fig. 711. a), already mentioned; and E. geniculatus (b) and sibiricus (c) would probably succeed equally well. The last grows on the sandy wastes of Siberia, and the preceding is found on the shores of Britain.

Chap. V.

Improvement of Lands already in a State of Culture.

4568. A profitable application of many of the practices recommended in the chapters of this and the foregoing Book may be made to many estates which have been long under cultivation. It is certain, indeed, that the majority of those who study our work will have that object more in view than the laying out or improvement of estates ab origine. Few are the estates in Britain in which the farm lands do not admit of increased value,
by rectifying the shape of fields, adjusting their size, improving the fences, draining the soil, or adding to the shelter; and few are the farmeries that may not be rendered more commodious. Of this, we shall give a few examples, after we have stated the general principles and modes of proceeding.

Sect. I. General Principles and Modes of Procedure, in improving Estates already more or less improved.

4569. The groundwork of improvement, on which a practical man may tread with safety and full effect, is an accurate delineation of the existing state, together with a faithful estimate of the present value, of the lands, and other particulars of an estate to be improved. A general map of the appropriated lands, readily exhibiting the several farms and fields as they lie, and showing the existing watercourses, embankments, fences, and buildings; the woodlands, standing waters, morasses, and moory grounds; the known mines and quarries; together with the commonable lands (if any) belonging to the estate, forms a comprehensive and useful subject of study to the practical improver. It is to him, what the map of a country is to a traveller, or a sea-chart to a navigator. If an estate is large, a faithful delineation of it will enable him in a few hours to set out with advantages, respecting the connections and dependencies of the whole and its several parts, which, were he deprived of such scientific assistance, as many days, weeks, or months could not furnish. If on the same plan appear the rental value of each field or parcel of land, and the annual produce of each mine, quarry, woodland, and productive water, in its present state, the preparatory information which science is capable of supplying may be considered as complete; and it remains with the artist to study with persevering attention the subject itself, in order to discover the species of improvements of which it is susceptible, and the suitable means of carrying them into effect.

4570. The species of improvements incident to landed property are numerous. They may, however, be classed under the following heads: — the improvement of the outline, and general consolidation of an estate by purchase, sale, or exchange; the improvement of the roads; of the mines and minerals; of the towns, villages, mills, and manufactories; of the waters; of the woods and plantations; and of the farmeries and farm lands. This last subject is the most common, and to it we shall devote the succeeding section. To discuss the other species of improvement, as applied to old estates, would necessarily include so much of what has already passed in review in the foregoing Book, as to be wearisome to the reader.

Sect. II. Improvement of Farmeries and Farm Lands.

4571. Farm lands are of more or less value according to the means of occupying them. Arable lands in particular require buildings and other conveniences proportioned to the size of a farm. We frequently see tenants curbed in their operations, and incurring a waste of produce, through the want of sufficient homesteads. On the other hand, we sometimes observe a prodigality of expenditure on farm buildings; thus not only sinking money unnecessarily, but incurring unnecessary expenses in subsequent repairs, by extending homesteads beyond the sizes of farms. In some cases, therefore, it will be found necessary to curtail the extent of farm buildings, as large barns; in others to enlarge the yards, and in many to add and re-arrange the whole. The subject therefore may be considered in regard to design and execution; but as we have already treated fully on laying out new farmeries, we shall here offer only a few general remarks as to alterations.

4572. In improving the plan of a farmery, the given intention is first to be maturely considered, and the several requisites to be carefully ascertained. The given site is next to be delineated, so as to show the existing buildings, yards, roads, and entrances; and then, by maturely studying the plan alternately with the site itself, the improver is to endeavour to trace out the most suitable alterations; all the while keeping in view the perfection of arrangement, the situation and value of the existing buildings, and the expenses of alteration; reconsidering the subject repeatedly, until the judgment be fully satisfied. It is much easier to plan and erect a new farmstead, than to improve one which is already erected. The former requires science and ingenuity only; the latter good sense and judgment also.

4573. In executing improvements on old farmeries, some difficulty occurs as to the incorporation of new and old materials. If the situation and plan are likely to be of permanent approval, the new erections may be made in the most substantial manner; keeping it in view that the old, which are repaired at the time, may afterwards be wholly renewed. But if the repairs and improvements are not to extend further than the duration of a lease, or till, by the expiration of various leases, some general plan of improvement can be determined on, then old materials may be used, or less permanent structures may be erected.
4574. As an example of adding part of a newly-enclosed common-field to a small anciently enclosed grass-farm (fig. 712), we give the following case:

4575. The farmery (a) and ancient enclosed fields (b), are separated from the common field by a road, and bounded on the other side by a lake. The soil is a soft black earth on a gravelly subsoil; the surface a gentle slope towards the lake. The farm-house is supposed to be already placed in this ancient part; and the object in view is to unite a large portion of the common field, when enclosed, to each ancient farm, so as to get a fair rent for the lands at the least expense. The soil of this common field is a light poor sand, with nearly a flat surface. The circumstances of the country are favourable to large farms, the climate is dry, and the situation such as to require shelter. The number of acres to be enclosed and added to this farm is 150. These will be most advantageously cultivated in six shifts of, 1, turnips (c); 2, barley (d); 3, artificial grasses (e); 4 and 5, the same (f, g); 6, wheat or oats (h). Each shift is proposed to be separated by a plantation for shelter, and no inferior divisions are made. In two of the plantations are field-barns, sheds, &c., where the corn grown on one half of the arable lands is threshed by a moveable threshing-machine, and the straw consumed by cattle. There are cottages at each of these barns for labourers to attend to the stock, &c. The ridges in each of the breaks or shifts are supposed to extend their whole length; or they may be ploughed as if the whole break were only one ridge, by which means not a moment is lost in turning at the ends, &c. Hereford or Devon oxen are supposed the beasts of labour on this farm.

4576. In place of the above rotation, wheat may be added after the second year of artificial grasses, and one shift kept entirely under saintfoin. This saintfoin division must of course be changed every sixth or seventh year. However, if a proper mixture of artificial grasses is sown, such as red, white, and yellow clover, rib-grass, burnet, saintfoin, timothy, cocksfoot, rye-grass, and soft-grass, the produce will be superior to that from either saintfoin or lucern alone, on a soil such as this, or even perhaps on any soil. Every agriculturist of observation must be aware that the efforts of annual and biennial plants are powerful for a few years at first, and that they uniformly produce a greater bulk than perennials: the latter seem to compensate for this temporary bulk by a steady durable produce.

4577. The old pasture near the house is supposed to be irrigated from the upper part of the lake, by a cut passing near the house. These pastures are particularly advantageous for early lambs, milk cows, &c. and for stock in general in seasons of great drought.

4578. Correcting the outlines of fields is one of the most obvious sources of amelioration on many, perhaps on most, estates. The advantages of proper sized and shaped enclosures have been fully pointed out, when treating of laying out farm lands, and in altering existing fences the same principles must be steadily kept in view; for though, unless by a total eradication of all the existing fences, every requisite may not be attainable, yet such a number may be gained as amply to compensate for the expense. In altering the shape and size of fields, besides the advantages resulting from the improvement in form, it will generally be found that a number of culturable acres may be added to the farm in proportion to the crookedness and width of the fences. Better drainage and roads will also be obtained, and where ornament is an object, a park-like appearance may be produced by leaving a single trees as part of what may have stood in the eradicated hedge-rows.
At an cramphof improving the shape and size of fields, we shall refer to a farm of 350 acres, situated in Middlesex. In this case, the fields were larger than usual, but the fences were in many parts from ten to fifteen yards in width, more resembling strips of copse wood than fences, as they contained hazel, dogwood, black and white thorns, wild roses, brambles, and a variety of native shrubs. The lines of these fences were so ill calculated for carrying oft’ the surface-water, that in one half of the fields there were open gutters for the discharge of the water collected in the hedge-row ditches.

In the centre of one field (25), for example, above an acre was rendered waste by the water from other fields (19, 20, and 21), which water, it is curious to remark, might, if led over the same acre agreeably to the principles of irrigation, have produced annually at least two loads and a half of good hay, in place of annually rendering the produce of this acre unmarketable.

In the farm, when altered (fig. 714.), the fields are more uniform in shape and size; their sides are parallel, and better adapted for ploughing the lands in straight ridges. All the surface-water is carried off by the open fence drains. Access is had to every field by the shortest possible road from the farm. Only two-thirds of the number of gates formerly required are requisite. Fifty acres are rendered useful which were formerly lost, or pernicious, by occupying space for which rent was paid, and by harbouring insects and noxious weeds; and as much rich vegetable earth is obtained from the old hedge banks as, spread abroad in every direction, may be said to manure at least ten acres. The whole is more open and healthful; and, from the number of single trees thrown into the fields, more elegant, and bearing a greater resemblance to a park. A part near the house (1, 2, 3) is in permanent pasture, and the rest (4, 5, 6, &c.) under a course of fallow, wheat, clover, beans, and wheat.
4582. As an example of altering the fields and consolidating a farm, we submit the case of a meadow farm, with the arable lands in a common field state. (fig. 715.) By an act of enclosure, these scattered arable lands (a) were exchanged for others adjoining the meadow grounds (fig. 716. b), and the whole ren-
dered more compact and commodious. This farm, being intersected by a public lane, affords an example in which no private roads are wanted. The size and shape of the fields were improved, and the broad fences reduced as in the preceding case, and attended with the same advantages in an agricultural point of view.

4583. But though in altering broad fences there are obvious and indubitable advantages to the farmer, yet, as justly observed by Loch, gain is not everything. "The fences on the Manxess of Stafford's estate," he says, "were liable to the same objection which is applicable to a great proportion of the counties of England. They are not composed of quick, at least but in a scanty degree; they for the most part consist of bushes, growing from the stump of every sort of forest-tree, intermixed with hazel, birch, horehound, maidenhair, elder, willow &c. They are planted on high and dry mounds, and thus are subject to constant decay. They occupy too much ground, provided agriculture alone were the occupation of life. But as they give great protection, when they thrive, to the game, they become an important object of preservation, insomuch as every thing must be of consequence which contributes to the sport, and has the effect of retaining the gentry of England much upon their estates. For this reason, it may occasionally be proper to consider of the best way to preserve those hedges at the least expense, in place of substituting more perfect ones in their stead; nor should one object exclusively be attended to in the agricultural improvements of so great and so wealthy a country." Such are Mr. Loch's ideas on game and hedges.

4584. When farm-lands are exposed to high winds, interspersing them with strips or masses of plantation is attended with obviously important advantages. Not only are such lands rendered more congenial to the growth of grass, and corn, and the health of pasturing animals, but the local climate is improved. The fact, that the climate may be thus improved, has, in very many instances, been sufficiently established. It is, indeed, astonishing how much better cattle thrive in fields even but moderately sheltered than they do in an open exposed country. In the breeding of cattle, a sheltered farm, or a sheltered corner in a farm, is a thing much prized; and, in instances where fields are taken by the season for the purpose of fattening, those most sheltered never fail to bring the highest rents, provided the soil is equal to that of the neighbouring fields which are not sheltered by trees.

If we enquire into the cause, we shall find, that it does not altogether depend on an early rise of grass, on account of the shelter afforded to the lands by the plantations; but likewise that cattle, which have it in their power, in cold seasons, to indulge in the kindly shelter afforded them by the trees, feed better; because their bodies are not pierced by the keen winds of spring and autumn, neither is the tender grass destroyed by the frosty blasts of March and April. (Plant. Kal. p. 121.)

4585. The operation of skreen plantations, in exposed situations, Marshal observes, is not merely that of giving shelter to the animals lodging immediately beneath them; but likewise that of breaking the uniform current of the wind, shattering the cutting blasts, and throwing them into eddies; thus mollifying the air to some distance from them. Living trees communicate a degree of actual warmth to the air which envelopes them. Where there is life there is warmth, not only in animal but in vegetable nature. The severest frost rarely affects the sap of trees. Hence it appears, that trees and shrubs properly disposed, in a bleak situation, tend to improve the lands so situated, in a threefold way, for the purposes of agriculture; namely, by giving shelter to stock; by breaking the currents of winds; and by communicating a degree of warmth or softness to the air, in calmer weather.

4586. The proper disposal of skreen plantations for this purpose is in lines across the most offensive winds, and in situations best calculated to break their force. Placed across valleys, dips, or more open plains, in bleak exposures, they may be of singular use; also on the ridges, as well as on the points and hangs, of hills.
PRACTICE OF AGRICULTURE. Part III.

4587. The width of screen plantations ought generally to be regulated by the value of the land for agricultural uses, and the advantages of the situation for the sale and delivery of timber. In ordinary cases, from two to four statute poles may be considered as an eligible width.

4588. The form of plantations for shelter, however, will not in every case be that of a stripe or belt of uniform width. In hilly, rocky, and other situations, different forms will suggest themselves, according to the situation and the objects in view. In rocky abrupt sites (fig. 717) the plantation will consist of a number of masses, of forms determined by the rocks and precipices, among which some of the most valuable pasture may be left as glades (4, c), for use, effect, and for the sake of game. Strips and hedges for sheltering, or separating arable lands, should be formed as much as possible in straight and parallel lines, in order not to increase the expense of tillage by short and irregular turnings. Straight strips, on regular surfaces, have the most varied appearance at a distance, than do the former; the outline against the sky is varied as much as that on the earth. In extensive hilly pastures, in which it is often desirable to produce shelter, and at the same time to plant only the most rocky and unproductive spots, the forms may be of the most irregular description; and by planting chiefly beneficial, and not only the blast acquiring additional current, but snow being liable to be blown through it for shelter. A larch plantation margined with spruce fins, and those headed at twelve or fifteen feet high, would afford the required shelter for a length of years. The fins, or pines, thus treated, would be induced to throw lateral boughs, and dress to the shelter; as also the larches, in their more advanced state of growth, would, by permitting the winter's winds to pass through the upper parts of the tree, break the current and mellow the blast.

4591. In more gradual situations, the beech, by retaining its leaves in winter, especially while it is young, forms a valuable screen. If the outer margins were kept in a state of coppice wood, and cut alternately, and the middle ranks suffered to rise as timber trees, the triple purpose of screen plantations might be attained in an eminent degree, and almost in perpetuity.

4592. In deep-sloped male districts, which not unfrequently want shelter, screens of oak might be managed in a similar way. Hollies, or other hardy evergreens, planted as underwood, in groves of either of the above descriptions, would, if suitable situations were assigned them, assist much in this intention.

4593. A tall impervious fence is, for the purpose of shelter to pasturing stock, nearly equal to a depth of coppice wood, and infinitely preferable to an open grove of timber trees; besides its additional use as a fence. There appears one species of fence which is peculiarly adapted to this purpose. This is the coppice mound hedge of Devonshire and South Wales; namely, a high wide bank or mound of earth, planted with coppice woods. This becomes, immediately on its erection, a shelter and a guard to pasturing grounds.

4594. The method of forming fences of this kind is to carry up a stratum of earth, between two sod terraces, "hatteries," or leaning somewhat inward, to the required height; and to plant on the top the roots and lower stems of coppice plants, gathered in wood, or on waste grounds; or nursery plants, adapted to the given situation. If the mound be carried to a full height, as five or six feet, and about that width at the top, and this be planted with strong plants, with stems cut off about two feet above the roots (in the usual practice of Devonshire), a sufficient fence is thus immediately formed against ordinary stock. But if the bank be lower, or if nursery plants be put in, a slight guard run along the outer brink on either side, and leaning outward over the face of the mound, is required (especially against sheep) till the plants get up. If a hedge of this kind is thus raised as a plantation fence (especially on the lower side of a slope), the outer side only requires to be fixed with sods; the hedge plants being set in a rough shelving bank, on the inner side.
4595. The species of hedge woods, proper for mound fences, depends entirely on the soil and situation. On mounds of bad soil, in a bleak situation, the furze stone affords much shelter, and a good fence. The sides being kept pruned, so as to show a close firm face rising above the top of the bank, it is a secure barrier, even against the wilder breeds of Welsh sheep. The beech is commonly planted in high exposed situations; and in places more gentle to the growth of wood, the hazel, the ash, and the oak are the ordinary plants of hedge mounds. The willow tribe have a quality which recommends them, in situations where they will flourish; they grow freely from cuttings, or mounds set in the ground; whereas, to secure the growth of ordinary coppice woods, rooted plants are required. The wild willow (Salix caprea) will grow in high and dry situations.

4596. On thin-soiled stony surfaces, tall mounds are difficult to raise; and there stone walls are not only built at a small expense, but are convenient receptacles for the stones with which the soil is encumbered. But a stone wall, unless it be carried up to an inordinate height, at a great expense, is useless as a screen; and may be said to be dangerous as such, in a bleak exposed situation, for as soon as the drifting snow has reached the top of the wall, on the windward side, it pours over it, and inevitably buries the sheep which may be seeking for shelter on the leeward side. Hence, in a situation where shelter is required, it is necessary that a stone fence should be backed with a screen plantation.

4597. To plant trees for shade may in some cases be requisite for agricultural purposes. Where this is the case, close plantations are seldom desirable, a free circulation of air being necessary to coolness; therefore trees with lofty stems, and large heads pruned to single stems, are preferable; the oak, elm, chestnut, and beech, for thick shade; the plane, acacia, and poplar, for shade of a lighter degree.

4598. An example of sheltering a hill farm by plantation, and at the same time improving the shape and size of fields, shall next be given. No farming subject affords better opportunities of introducing hedge-rows, and strips of planting, than hill farms. The one under consideration (fig. 719.) is a small estate farmed by its owner; it consists of nearly 370 acres; and is situated in an elevated, picturesque part of a central English county. The soil is partly a flinty loam or chalk, and partly a strong rich soil, incumbered on clay. The fields are very irregular, bounded by strips of timber and copse. By the alterations and additions proposed (fig. 720.), all the most hilly and distant spots will be kept in permanent pasture; and the exposed and abrupt places, angles, &c. planted chiefly with oaks for copse, and beech for timber and shelter.

4599. On hill farms in Scotland, where shelter cannot be given to grass and stock by plantations, small circular inclosures have been adopted for that purpose. The diameter of these circles is from 10 to 30...
feet, the height of the wall six or eight feet, and a conical roof is placed on them, and covered with turf; but many inclosures of this kind are formed without roofs. They are called in Selkirkshire stools, and were brought into notice, in 1822, by Captain, now Lord Napier, in his Treatise on Store Farming, a work to which we shall have recourse in a subsequent section.

**CHAP. VI.**

Execution of Improvements.

4600. The mode in which improvements are executed is a point of very considerable importance, and may materially affect their success as well as their expense. We shall first consider the different modes of execution, and next offer some general cautions to be kept in view in undertaking extensive works.

**SECT. I. Different Modes of procuring the Execution of Improvements on Estates.**

4601. The necessary preliminary to the execution of an improvement, is a calculation of the advantages to arise from it, and an estimate of the expense of carrying it into effect. If the former, taken in their full extent, do not exceed the latter, the proposed alteration cannot, in a private view, be considered as an improvement. The next point to be ascertained is the practicability, under the given circumstances of a case, of executing the plan under consideration. There are three things essential to the due execution of an improvement. 1st, an undertaker, or a person of skill, leisure, and activity, to direct the undertaking; 2d, men and animals with which to prosecute the work; 3d, money, or other means of answering the required expenditure. A deficiency in any one of these may, by frustrating a well-plained work after its commencement, be the cause not only of its failure, but of time, money, and credit being lost.

Improvements may be executed by the proprietor, either directly; gradually, by economical arrangements; or remotely, to a certain extent, by moral and intellectual means.

4602. To execute improvements directly, all that is necessary is to employ a steward or manager of adequate abilities and integrity, and supply him with the requisite plans, men, and money. This will generally be found the best mode of forming new roads, new plantations, opening new quarries or mineral pits, altering the course of waters, and all such creations or alterations as are not included in the improvement of farm lands.

4603. To procure the gradual execution of improvements on farm lands, various arrangements may be made with the tenants; for example, by granting long leases; letting them find the requisites of improvement, and take the advantages during their terms; by granting shorter leases, with a covenant of remuneration for the remainder of such improvements as they may have made, at the time of quitting; by granting leases, at a low rent, for the first years of the term, to give the tenants time and ability to improve at their own expense; by advancing money to tenants at will, or, which is the same, making allowances of rent for specified improvements, to be executed by them under the inspection and control of the manager, they paying interest for the money advanced or allowed; by employing workmen on tenant's farms; the tenants in like manner paying interest on the money expended. The usual interest, till lately, was six per cent; thus estimating the value of the improvement at sixteen years' purchase.

4604. The moral and intellectual means of improving farm lands consists, as Marshal has observed, in enlightening the minds of tenants. Though this mode is but of slow operation, and respects improvements in modes of culture, rather than such as require great outlay; yet it deserves notice in this place, as necessary to second the efforts of the landlord.

4605. Farmers, as moral and intellectual agents, may be divided into reading men, and illiterate beings: the first class derive hints for improvement from books; but the second can only, if at all, derive benefit from example.

4606. With respect to improving farmers by books,—agricultural newspapers, magazines, and county surveys, are probably what would be read with most eagerness; and as such works abound in statements of what actually has taken place in different situations, by farmers like themselves, perhaps they are the most likely to stimulate to exertion. Historical relations of the agriculture of other countries are also generally interesting to agriculturists; and though no great professional benefit is to be derived from them, yet they tend to enlarge and liberalise the mind, and promote a taste for knowledge. Under these circumstances, it may be worth of consideration whether an agricultural library might not be established in the steward's office, on very extensive estates, for the use of tenants and all other persons belonging to the estate who chose to read from it. Immerging libraries for the use both of farmers and their servants, or, indeed, of whoever chooses to use them, have for some time been established, and extensively used in East Lothian, and they are gradually being adopted in other counties both in Scotland and England.

4607. The establishment of schools for the children of the lower class of tenants, and of cottagers of every description, is an obvious and important source of moral and intellectual improvement; and considering it as devoted by experience and the most competent judges, that the education of the lower classes will tend greatly to their amelioration and the benefit of society at large, we are of opinion that, wherever they are not already established, they should be introduced. Working schools, somewhat in the German manner, both for boys and girls, would also be a material improvement in such districts as are behind in a taste for cleanliness, fireside comforts, cookery, and dress.
EXECUTION of IMPROVEMENTS.

4608. Examples as stimuli to improvement may be exhibited in various ways: by etting a farm to a tenant of superior energy, or from a more improved district; by exhibiting improved implements and operations on one particular farm; by an itinerant ploughman of abilities, accompanied by a smith and carpenter, and with some implements, to go round the estate and instruct each tenant on his own farm; and finally, and perhaps preferably, by inducing every farmer to make a tour into some other district once a year.

4609. In addition to these modes, appropriate as we consider for two different classes of tenants, Marshal's spirit, or calculating upon improvements in a spirit of sufficient energy and intelligence. They are to be adopted in various ways, by a proprietor, or by the manager of an estate, who has a knowledge of rural affairs, and who possesses the good will and confidence of its tenants.

4610 By personal attention alone much is to be done. By reviewing an estate, once or twice a year; by conversing with each tenant in looking over his farm; and by duly noticing the instances of good management which rise to the eye, and condemning those which are bad; vanity and fear, two powerful stimulants to heighten emulation, and inculcate the love of improvement, while shame will scarcely fail to bring up the more deserving of the inferior ranks. If, after repeated exhortations, an inirresistible slime be discharged as such, and he farm given to another, professedly for his emulations as a practised husbandman, an alarm will presently be spread over the estate, and none, but those who deserve to be discharged, will long remain in the field of bad management.

4611. Even by conversation, well directed, something may be done. If, instead of, on the one hand, collecting tenants to the audit, as sheep to the shearing, and sending them away, as sheep that are shorn; or, on the other, providing for them a sumptuous entertainment, and committing them to their fate in state of intoxication; a reapst suited to their conditions and habits of life were set before them; and, after this, the conversation bent towards agriculture, by distributing presents to superior managers, and specifying the particulars of excellence for which the rewards or acknowledgments were severally bestowed; a spirit of emulation could not fail to arise among the higher classes; while the minds of the lower order of tenants, and of the whole, would be stimulated and improved by the conversation.

4612. By encouraging leading men in different parts of a large estate, men who are looked up to by ordinary tenants; by holding out these as patterns to the rest, furnishing them with superior breeds of stock; by supplying them with superior varieties of crops, and with implements of improved constructions: and, in reclus and backward districts, much may be done by tempting good men, and expert workmen, from districts of a kindred nature, but under a better system of cultivation, to settle upon an estate.

4613. By an experimental farm, to try new breeds of stock, new crops, new implements, new operations, and new plans of management; such as ordinary tenants ought not to attempt, before they have seen them tried. The demesne lands are here demesne, for the purpose of the experiment; they are to be appropriated to a nursery of improvements, for the use of the estate; to be professedly held out as such, and be constantly open to the tenants; more particularly to the exemplary practitioners, the leading men, just the estate, upon which all fortune, who is, too, can introduce improvements among the lower classes of an ignorant and prejudiced tenantry: it is in vain for a proprietor to attempt it. On the contrary, the attempt seldom fails to alarm, disgust, and prevent the growth of spontaneous improve-

4614. Under the present plan of demesne farming, the tenants see expensive works going forward, which they know they cannot copy, and hear of extraordinary profits, by particular articles, which they are certain cannot be obtained by any regular course of business. They therefore conclude that the whole is meant to protect the possessors of the rents, or to improve their farm, at the expense of their value. Whereas, if the demesne lands were held out, as trial grounds, for their immediate benefit, and conducted in a manner intelligible to them, they would not fail to visit them. Instead of large proprietors attempting to rival the nearest of their tenants, in farming for pecuniary profit, which, on a fair calculation, they rarely, if ever, obtain; let their views in agriculture be professedly and effectively directed toward the pecuniary advantages of their tenants; for from these alone can their own arise, in any degree that is entitled to the attentions of men of fortune. Instead of boasting of the price of a bullock, or the produce of a field, let it be the pride of him who possesses an extent of landed property, to speak of the flourishing condition of his estates at large, the number of superior managers that he can count upon them, and the value of the improvements which he has been the happy means of diffusing among them. Leave it to professional men, to yeomanry and the higher class of tenants, to carry on the improvements, and incorporate with their practice pecuniary advantages in their constitution. If the tenant can be taken in examples to inferior tenantry. This is strictly their province; and their highest and best view in life. It has been through this order of men, chiefly or wholly, that valuable improvements in agriculture have been made in England, and made of general use.

4615. The possession of an extent of territory has higher objects in view, and a more elevated station to fill. As a superior member of society, it may be said, he has still higher views than those of aggrandising his own income. But how can a man of fortune fill that which may well be termed his legitimate station in life, with the importance of his private, by promoting the general welfare; by rendering not one field, or one farm, but every farm upon it productive? This is, indeed, being faithfully at his post; and it is a good office in society, which is the more incumbent upon him, as no other man on earth can of right perform it, valuable as it is to the public.

Sect. II. General Cautions on the Subject of executing Improvements.

4616. No work can be prudently commenced until the plan be fully matured, not in idea only, but in diagrams, and in models, if the subject requires them; in order that every bearing and every hinge may be sufficiently foreknown: the site of improvement being reverted to, again and again, with the draught or the model in hand, until the judgment be satisfied and the mind be inspired with confidence. If a proprietor have not yet acquired sufficient judgment within himself, let him consult some one man, or one council of men, in whose knowledge and judgment he can confide; and thus fix a rallying point. Having brought his plan to a degree of maturity, in this private manner, he may then venture to publish it; and endeavour to improve it, by the advice of its friends, and the animadversions of its enemies.

4617. If a proprietor wants judgment himself, and a friend to supply it, let him not attempt the more difficult works of improvement. Yet how often we see, both in public and private life, men engaged in arduous undertakings, embarked on the wide ocean of business, without rudder or compass to guide them, depending on casual information, to help them on their way! They are consequently ever of opinion with the last persons they converse with. Such men's decisions and operations are always wrong: and for
an obvious reason. They consult those who are best able to inform them, first; and re-
ceive their last impressions from those who are least capable to give them. Men who 
have neither judgment in themselves, nor any standard of practice to rally at, are liable 
to be led astray by the plausible schemes of theorists, the greater part of whom know 
nothing of the practical part of business, and who, by their calculations, both of expense 
in the outlay and of profit in the return, deceive both themselves and their friends or em-
ployers; some also may have sinister designs in view; though we believe the errors of 
speculative men are in most cases owing to their being endowed with more imagination 
than judgment.

4618. The execution of the different improvements of which an estate has been found 
susceptible being determined on, it is always advisable to begin with one which is ob-
vious; which may be effected with the greatest certainty; which will repay most amply 
the expenses of carrying it into effect; or which leads to other improvements, as em-
bankment, drainage, &c. To attempt a doubtful project, while plans which are obvious 
and certain remain unexecuted; to try experiments before the list of known improve-
ments has been gone through; is seldom to be recommended, though it might sometimes 
turn out to be right.

4619. All rural operations are more or less public, and as it were performed on a stage; 
and spectators fail not to criticise. If an experiment should prove abortive, or a pro-
posed improvement turn out to be false, the ardour of the improver will be liable to be 
damped, his people to be discontented (as partaking in the discredit), and the expecting 
public around him to be disappointed. A few miscarriages, in the outset, might frustrate 
the best intentions and the most profitable schemes. But if, by prosecuting plain and 
certain improvements, a man once gain his own confidence, as well as that of the 
people about him, he may then venture to explore less beaten paths; and this he will 
be able to do with greater caution, and more probability of success, by the experience 
already gained; this being a further motive for pursuing the line of conduct here 
suggested.

4620. All works of improvement should be executed with vigour. Many falter in the 
midst of well-planned works, either, through the want of foresight or of business-like 
execution; in consequence, the money already expended lies dead, and the works are in-
jured by the delay. Some works, as embankments and drainages, may be ruined by the 
slightest neglect or relaxation; and, indeed, as Marshal observes, we see, in every depart-
ment of the kingdom, these and other works deserted, and left to moulder into nuisances 
or disreputable eyesores.

4621. In carrying on a work, execute every thing substantially, and in a workman-like 
manner. Too often a false economy leads to the subversion of this principle. To save a 
few pounds in the first cost, materials of an inferior quality are laid in, or a quantity 
used insufficient to give the required substance and strength to the work. By either of 
these imprudences, its duration is abridged; and the eventual loss, by repairs and re-
newal, may be ten times greater than the sum injudiciously saved in the original erection. 
Nevertheless, to increase the evil of these ill-judged savings, inferior workmen are em-
ployed; or sufficient workmen at inferior prices, at which they cannot afford to make 
good work, nor can a superintendent urge them to make it under such circumstances. 
Consequently the work is ill performed, its duration is still more abridged, and a further 
loss is incurred by injudicious saving.

4622. There are cases in which temporary works only are required. A lease-tenant, for 
instance, wants to make an improvement which will last as long as his lease, without 
caring about its further duration. In such a case, it may be well-judged frugality and 
admissible "cleverness in business," to work up cheap materials in a cheap way; but it 
seldom can be right in the proprietor of a hereditary estate, whose interest in it may be 
said to be perpetual, to proceed in the same manner. His best policy is to take favour-
able opportunities of laying in good materials at moderate prices; to use them when 
duly seasoned; and to employ good workmen at such prices as cannot furnish an excuse 
for bad workmanship, and will warrant him to enforce good.

4623. Accomplish one work before another is commenced. A work may be considered 
as accomplished when the chief difficulties are surmounted, and the chief cost expended; 
and, till this is the case, it cannot be prudent to embark in another. By avoiding em-
barrassments, the execution of improvements becomes a present pleasure, as well as a 
source of future profit; no half-finished works are left as monuments of disgrace to an 
estate and its owner; no time nor interest of money is lost; every work is brought into 
action and profit as it is finished; and if, as it frequently will happen with the most 
prudent calculators, the estimated sum has been exceeded, due time may be taken to let 
the fund of improvement accumulate, so as to enable it to discharge the arear, and to fur-
nish, as wanted, the estimated sums requisite for the succeeding work.
BOOK IV.

MANAGEMENT OF LANDED PROPERTY.

4624. The management of an extensive landed estate, like that of every other great property, is a business both of talent and integrity. In former times, when every proprietor may be said to have cultivated the whole of his agricultural territory, it constituted his whole occupation, when not engaged in war; or required a host of managers, if he was a man of the first rank. On the continent, and especially in Russia and Hungary, where estates are of enormous extent, and wholly farmed by the proprietor, the largest estates, as we have seen (621.), are managed by a court of directors, and an executive department, with a numerous body of superintendent officers, artists, and artisans. A better system is now adopted in this country, in consequence of the creation of professional farmers, who, taking large portions of territory from the owner for a certain number of years at a fixed rent, and on certain stipulations for mutual security, occasion little trouble to the proprietor, during that period, than receiving payments. Hence it is that the management of estates in Britain, though important, is a more simple business than in any other country.

4625. Where there are only tenanted holdings, the business of management is very simple; where there are woodlands, it requires a person to look after that department; and where there are waters, quarries, and mines, a greater number of subordinate officers are requisite. But what often occasions most expense, and at the same time is attended with the least profit, is the management of the abstract rights belonging to an estate; such as manorial rights, quit-rents, and other feudal or antiquated trifles or absurdities, which require courts to be held, and lawyers and other officers to be called in to assist. The only British author who has digested the business of managing estates into a regular system is Marshal, and we shall follow him in considering this subject:—1st, as to the superintendents on the executive establishment of an estate; and, 2dly, as to the general business of management.

Chap. I. Superintendents, or Executive Establishment of an Estate.

4626. Though every man who cannot manage his own estate in all important matters, deserves to lose it, yet, as extensive proprietors generally have their properties situated in different parts of the country, and have, besides, public duties to attend to, certain subordinate managers become necessary. In The Code of Agriculture it is stated, that no individual having a large estate is equal to the task of managing it, unless he is in the prime of life, dedicates his whole time to the business, and gives up every other occupation. It is there stated to have been found expedient, by the proprietor of an estate of great extent, to nominate two or three commissioners to assist him in his management. Under the superintendence of such commissioners, it is said, the affairs of a great property would be as well conducted as on the best managed small or moderate-sized estates; while the duties of the proprietor would principally be to carry the exercise of true benevolence into effect, which would consist in softening severe decisions; or in granting those marks of approbation and reward which, when bestowed by the proprietor himself, are the most likely to produce beneficial consequences. (Code, &c. App. 58.) Such may be the case on a few estates in the British isles not yet brought into a regular system of improvement, and about to be remodelled, of which a grand example occurs in the immense property of the Marquess of Stafford: but, in the great majority of cases, to each estate a manager of qualifications suited to its extent and duties, and a general receiver and controller in the capital or metropolis (if the proprietor and his banker cannot effect these duties between them) are all that is requisite. We shall first offer a few remarks on the qualifications and duties of managers, and next on the place of business and its requisites.

Sect. I. Steward or Manager of an Estate, and his Assistants.

4627. The head manager of an estate ought unquestionably to be the proprietor himself, or his representative, if a minor or otherwise incompetent. Next to the proprietor is his acting man of business, with proper assistants; together with such professional men as advisers as the circumstances of business may render necessary. A tenanted estate differs widely from other species of property; as giving power and authority over persons as well as things. It has, therefore, a dignity and a set of duties attached to it,
which are peculiar to itself. A man who receives ten thousand pounds a year from the public funds, for instance, is an insulated being, compared with him who receives the same income from landed property, and who is one of society's best members, provided his affairs are judiciously conducted. On the contrary, if, regardless of the dignity and the duties of his station, he lives but to dissipate his income, leaving the government of his estates and their inhabitants to those whose interest and honour are unconcerned in their welfare, or to those whose best interests lie in their derangement, he becomes at once an enemy to himself, to his family, and to the community. As unpardonable it would be in the possessor of a kingdom to be ignorant of state affairs, and unmindful of the ministers who reside about his court; or in the commanding officer of a regiment to be a stranger to his men, a priest to his parishioners, or a shepherd to his flock; as for the possessor of a tenanted estate to be ignorant of territorial concerns, and a stranger to his lands and their occupants.

4628. Though it be an essential part of the duty of a man of fortune to be intimately acquainted with his own affairs, it does not follow that he should be absorbed in them, and neglect his duties as a superior member of society. In all matters of government and command, subordination is essential to good order and success. A commander in chief does not act as pioneer, nor does a naval commander reef his sails, or heave his anchor. Each has his subordinate officers to convey his commands, and men to execute them. But it is essentially necessary that the former should be well acquainted with military, the latter with naval, affairs. Every heir apparent, therefore, to a large landed property, should be regularly, or at least more or less, bred up in the knowledge of rural affairs, so as to fill with honour and profit the high station he has in view. But if the possessor of an estate has not been fortunately initiated in the knowledge which belongs to his station, the task of acquiring it is far from great.

4629. On a large estate we generally find a resident manager, a land steward, a man who has some knowledge of what is termed country business, and who acts under the control of his employer, or of a confidential friend, who is more conversant in rural concerns; or perhaps of a law agent, who knows less of them; or such residing steward, especially of a detached estate which lies at some distance from the residence of its proprietor, acts without control. In the last case, if he is a man of judgment, it is fortunate both for the landlord and tenant: but, on the contrary, if such possessor manager wants those requisite qualifications, the consequence becomes mischievous to the lands, their occupiers, their proprietors, and the community.

4630. The requisite acquirements of an acting manager, according to Marshal, are, a knowledge of agriculture, surveying, planting, some knowledge of mechanics, natural history, and skill in accounts. Agriculture is the only firm foundation on which the other required attainments can be securely reposed. It is not more essentially valuable in the superintendence than in the improvement of an estate. It is difficult to become an accurate judge of the value of lands without a practical knowledge of their uses; nor can any man without it properly appreciate the management of occupiers, much less assist them in correcting their errors, and improving their practice.

4631. Land-surveying is a requisite qualification. Not so much, however, for the purpose of measuring and mapping an estate at large, as for checking and correcting the works of professional men, as well as to assist in laying out its lands to advantage.

4632. Planting, and the management of woodlands, are acquirements that cannot be dispensed with. Nor should his knowledge and attention be confined to the surface of the estate entrusted to his care; he ought to have some acquaintance with natural history, chemistry, and experimental philosophy, to enable him to form just notions on the subject of the subterranean productions which it may contain.

4633. Some knowledge of mechanics, and other sciences that are requisite to the business of an engineer, may be highly useful in prosecuting the improvements incident to landed property.

4634. A competent knowledge of rural architecture, the doctrine of the strength of materials, and the superintendence of artificers, may be said to be of daily use.

4635. A thorough knowledge of accounts is essentially requisite to the manager of a landed estate.

4636. He should be a man of good character, of upright principles, and conciliatory manners; to set an example of good conduct to the tenants, and to become their common counsellor and peace-maker, in those trifling disputes which never fail to arise among the occupiers of adjoining land; and which too frequently bring on serious quarrels and lawsuits, that end in the ruin, not only of themselves, but of the tenements they occupy. A proprietor has, therefore, an interest in checking such disputes in the bud; and no man can do this with so much effect as a manager in whom they have a proper confidence, and who possesses a due share of popularity on the estate.

4637. The acting manager requires certain assistants on a large estate; especially if it lies in detached and scattered parts. Those in general use are a ground officer and clerk.

4638. A land-reeve, woodward, or ground officer, is required on each district or department of a large estate; to attend not only to the woods and hedge-timber, but to the state of the fences, gates, buildings, private roads, driftways, and watercourses; also to the stocking of commons (if any), and enrochments of every kind; as well as to prevent or detect waste and spoil in general, whether by the tenants of the estate, or others; and to report the same to the manager.

4639. The office-clerk, book-keeper, or under steward, is employed to form registers,
make out rentals, &c. and keep the accounts of the estate; as well as to assist the manager in his more active employments; also to act as his substitute in case of sickness, or absence; and to become his successor in the event of his death, or other termination of his stewardship.

4610. A law assistant, solicitor, or attorney, may next be considered as requisite to the good management of a landed estate. For although much is to be done by judicious regulations, and the timely interposition and advice of a resident manager, such are the frailties of human nature, that, in a state of civilised society, and of property, legal assistance will sometimes be necessary. The error of country gentlemen consists, not in employing lawyers, but in committing the management of their landed estates to them. The employment of law agents as land stewards, however, is not without some reason. Farmers are not for the most part sufficiently skilled in accounts for taking the charge of a large estate; and such of them as are capable, are commonly men of capital, and would not exchange their situation for the less independent one of a land steward. The division of labour, in the case of large estates, is not without its use, and is recognised in practice. A law agent collects the rents and keeps the accounts, often on a very small salary; and in questions of a practical nature, such as the valuation of new leases, the modes of cropping, &c. he advises with a surveyor or land valuer. After all, however, a well chosen land-steward to reside upon the estate, and to consult, when necessary, with a lawyer, must be the best plan, even though his salary be higher than that of the law agent, who commonly acts for several proprietors, does not reside on any of their estates, and very likely, as we think, cannot do them justice.

4611. In the feudal system, under which every manor court was a court of law, we may perceive the origin of law land-stewards. It is allowed by the best agricultural writers in Europe (Chateauneuf, Thaer, Thouin, Mathieu de Dombasle, Sigismondi, Jouvellanos, Young, Marshal, Brown, Coventry, &c.), that these men by their rigid adherence to precedent in the clauses of leases, have contributed most materially to retard the progress of agricultural improvement.

4612. The land-surveyor is another professional man, whom the superintendent of an estate may want to call in occasionally. Not merely to measure and map the whole or parts of the estate, but to assist in matters of arbitration, and the amicable settlement of disputes; or to act himself, as valuer or referee.

SECT. II. Land Steward's Place of Business, and what belongs to it.

4613. A manager's place of business may be considered in regard to its situation, accommodations, and appropriate professional furniture.

4614. The situation of the place of business should be under the roof of the proprietor's principal residence; round which, and in its neighbourhood, some considerable parts of his estates may be supposed (as they ever ought) to lie. If a large bulk of his property lie at too great a distance for tenants to attend at the principal office, and if on this he has a secondary residence, an inferior office is there required for such detached part. And it may be laid down as a rule, in the management of landed property, Marshal observes, that every distant part of an estate ought to have a place upon it (be it ever so humble) in which its possessor may spend a few days comfortably; to diffuse over it a spirit of good order and emulation. He has known the most neglected and almost savage spot, such as are many landed estates in Ireland, reclaimed and put in a train of improvement by this easy method.

4615. The accommodations requisite for a principal office are, a commodious business room, a small ante-room; and a safe-keep, or strong room, fire proof, for the more valuable documents.

4616. The professional furniture with which an office of this description requires to be supplied are maps, rental-books, books of valuation, register, legal papers, and some others.

4617. A general map of the whole estate on a large scale is an obvious requisite; and portable separate maps, with accompanying registers and other descriptive particulars, are useful in proportion as improvements may be in contemplation.

4618. Books of valuation are essential, especially where there are numerous small holdings on short terms. In these registers are contained the number, name, admeasurement, and estimated value of each field, and of every parcel of land, as well as of each cottage or other building not being part of a farmstead, on the several distinct parts or districts of the estate. The valuations being inserted in columns, as they arise, whether by general surveys, or incidentally, headed with the names of their respective valuers, so that whenever a farm is to be relet, these columns may be consulted, and its real value fixed in a resurvey with the greatest exactness.

4619. A general register of timber trees, copsewood, and young plantations is particularly wanted where there is much beechwood timber. Marshal directs to specify in this register the number of timber trees in each wood, grove, hedgerow, and area, with the species, number, and admeasurement of each tree. He also recommends separate pocket-books, containing the particulars of each division, or of a number of contiguous divisions, for the occasional use of the manager and stewards.

4620. Contracts, agreements, accounts, letters on business, and other documents, should be intelligibly endorsed, dated or numbered, and arranged so as to be easily referred to. A book of abstracts, or heads of papers of greater importance, should be made out to be referred to on ordinary occasions, and likewise
to serve as an index to the originals, which require a more secure repository than a common business
room.

4553. Legal documents, such as title deeds, legal decisions, awards of arbitration, counterparts of leases,
securities, cash, bills, passed accounts, &c., as being the most important objects, should be carefully depo-
sited in the safety-chest or strong room.

4554. Portable registers of the tenants of landed estates, in convenient pocket volumes, with maps on a small scale
heading every farm, are, according to Marshal, who seems to have looked upon tenants as placed in a state
of continual hostility with their landlords, a most invaluable description of books both for the manager and
his employer. Two opposite pages being appropriated to each farm with its map, the following information
should be given:

Name of the farm and its number of acres. The name of the tenant and the existing rent. The tenancy: if on lease, the term of expiring. Any extraordinary covenant of the lease. The number of cottages let with the farm. The number of timber trees growing on it. The number of orchard trees growing on it.

4555. Add, among other things, the following, viz.:

The repairs more immediately wanted. The improvements of which the whole is suscep-
tible. The agreements entered into with the tenant. The permissions granted him. The injunctions delivered to him. With a hint as to his personal character, and the number and general character of his family.

4556. The trouble of forming an abstract of this kind, or of renewing it when filled, or in order to adapt it to the varying circumstances of the several farms, is inconsiderable, compared with its uses, which are not only obvious in theory, but are fully established in practice. On returning to an estate, after twelve months' absence, Marshal has generally found, that, by consulting a register of this sort, and, through its means, making systematic enquiries respecting the incidents that have occurred on the several farms during his absence; he, in this summary way, and before he entered upon a fresh view, became better acquainted not only with the general interests, but with the more ordinary business, of the estate, than the acting manager, who had constantly resided upon it, without such a remembrancer. This abstract or remembrancer, he says, ought not to comprehend tenanted farms only; but should comprise woodlands, quarries, the demesne, &c. in hand; as well as the more important improvements going on: each of which ought to have its separate folio assigned it. To a proprietor, or his confidential friend, who only goes over his estate occasionally, such an intelligent companion is essentially serviceable. He cannot profit-
ably, nor safely are he with, an acting manager, or other agent or officer of the estate, until he has consulted so infallible an oracle. The utility of such a register, while a proprietor is absent from his estate, if he can be said to be so, with such a faithful mirror in his possession, is too obvious to require explanation.

4557. Among the instruments necessary for a manager's office, may be included those requisite for sur-
veying, mapping, levelling, measuring timber, and every description of country work, together with
boring machines, draught measurers, weighing scales, some chemical tests, models, and such other articles
as may be required or rendered useful by particular circumstances.

4558. An agricultural library may be considered an essential requisite; including works on rural archi-
tecture, the prices and measuring of work, and other fluctuating matters; and one of the best encyclo-
pedias of universal knowledge. We have already suggested an important use to which such a library
might be applied.

4559. Such an establishment and place of business as has been described, we agree with Marshal in thinking, many will consider as in some degree superfluous or extravagant. In many cases we admit it would be so; but it is impossible to determine what things can be done without, unless a particular case were given. Such a minute register of farms, for example, would be quite ridiculous on an estate in East Lothian, where tenants are of sufficient wealth and respectability of manners to be treated as men; and not watched and schooled like those which Marshal seems generally to have in view. As tenants of land become enlightened, they will be very differently treated from what in many places they are at present. As a proof of this, we have only to compare one dis-
tric of country with another. In East Lothian, Berwickshire, and some other parts of
Scotland, the farmers are as intelligent as their landlords; and the transactions which take place between them resemble the transactions which take place between one mercantile man and another. In districts where the tenant has little capital, and where he is sunk in ignorance, he ranks with the labourer, and occupies his farm by a sort of suf-
fERENCE. It is a pity that the ignorance and seclusion of such men do not admit of their comparing their state with that of others possessing no greater capital, but more know-
ledge and skill: it is a pity, we say, for the sake of their children, whom they might thus be induced to educate.

Chapter II.

Duties of Managers of Estates.

4658. The various duties of the manager, or the proprietor, of a landed estate, may be
considered under the heads of general business, business with tenants, and auditing
accounts.
Sect. I. General Principles of Business considered relatively to Land-Stewardship.

4659. The first and most general principle, in this and every other department of business, is to embrace readily the several matters as they occur; and not to put them off from time to time, until they accumulate, and render the task difficult and irksome. The only artifice, it may be said, which a man of character can well employ in business is that of endeavouring to render it pleasurable; and, by meeting it cheerfully, as it rises, or as it becomes ripe for despatch, this desirable end will generally be attained: for, in that state a man not only enters upon it with pleasure himself, but he will generally find his opponent in the same temper of mind. Whereas, through delay, misunderstandings, idle tales, and groundless surmises are liable to intervene; the minds of both to be soured; a distant coolness to take place between them; and a barrier to be raised, which, though altogether imaginary, nothing but the mystic wand of the law may be able to remove.

4660. There are three distinct methods of conducting business. The first is that in which the parties meet, with fair intentions, to find out the point of equity, and there to close. In the second, they enter upon business, guarded with cunning, and armed with trick and artifice, as gamblers draw round a table, to take every advantage, fair or otherwise, which they can effect with impunity. The last method lies in the courts of law and equity.

4661. A business founded on honourable intentions is the only one in which a man of honour can voluntarily appear. Here honest men come, as indifferent persons, to arbitrate the matter in reference. In every settlement between man and man, there is a point of equity and right, which all good men are desirous to find; and when men of liberal minds fortunately meet and join in the search, it is seldom difficult to be discovered. Should some little difference of opinion arise, let them call in an umpire to decide between them; or leave the whole to the decision of three capable and disinterested men.

4662. A man of strict integrity may become entangled in business with a man of honey principles. In this case, it behoves him to be upon his guard; but still to enter into the negotiation with temper and civility. There is something in the likeness in affairs of business which cannot be departed from on any occasion. Interruptions and skirmishes frequently arise, especially between men who are of keen sensibility, and who (though passably honest) are tenacious of their own interests, from mere matter of punctilio. The mind of either being once soured by neglect, or ruffled by disrespectful behaviour, the smooth path of peaceful negotiation is broken up, a spirit of warfare is roused, and advantages are taken, or attempted, which calm reason would not have suggested. Hence, when men of unequal degree are brought together in business, it is incumbent on the superior to set the example of liberality and civility of demeanour.

4663. In extreme cases there is no resource but the law; and here the most that an honest man can do is to procure, without loss of time, the best advice; and to spare no exertion or useful expense in bringing the dangerous and fornicating business to a speedy conclusion. Not only is a man's property endangered, while it is tossed on the troubled sea of the law; but his time and attention are led astray, and his peace of mind is liable to be broken in upon, thus deranging his ordinary concerns, and disturbing the stream of life. How much legal dispute might be prevented by a timely attention to business!

4664. In forming connections in business, select the man who has a character to lose. This principle should be invariably acted on: for if a man of established good character be properly treated, and determinately closed in with in case he demur or swerve from the right line of conduct, he will not forget his good name by doing a disreputable action; and must therefore come forward to the point of equity and justice.

Sect. II. Management of Tenants.

4665. The general treatment of tenants and cottagers may be considered as the most important part of every land-steward's occupation: it includes the mode and conditions of letting lands, and the time and manner of receiving rents. The idea of a landlord or his agents managing his tenants does certainly on the face of it appear an absurdity. The tenant is not more obliged to the landlord than the landlord is to the tenant; and therefore both parties being on an equality in point of obligation, the one ought not to require or have the power to manage the other. This power is given, however, by the ignorance of one of the parties, and the existing monopoly in favour of the other; and till these are done away with, by education and political changes, the ignorant part of farmers will always be managed by their landlords.

Subsect. 1. Proper Treatment of Tenants.

4666. On every large hereditary estate, there are established customs and usages, to which the proprietor and the occupants consider themselves mutually amenable, though no legal contracts may subsist between them. Wherever imperfect leases, or other legal agreements exist, still there is generally much left for custom and usage to determine.

Though some of these may be improper, yet they ought to be strictly observed by its superintendent, until better can be placed in their stead; not merely on the score of moral justice, but, in the same observance, to set an example of integrity and good faith to the tenants. If a superintendent imprudently break through a custom or a covenant, what can he say to a tenant who follows his example?

4667. A manager ought to set an example to the tenants under his care of liberality and kindness. This is more especially applicable to the case of cottagers and others who rent small holdings. There are numberless small favours which he can bestow upon them without loss, and many with eventual advantage to the estate. A spirited improv-
ing tenant should be refused nothing that he can reasonably ask; should have favours voluntarily conferred upon him, not merely as a reward for the services which he individually is rendering the estate, but to induce its other tenants to follow his example, and to make known to the whole that their conduct is observed, and distinctions made between good and bad managers.

4668. *Estates, like men, have their good and bad characters.* No skilful farmer who has a capital to lose, will take up his residence on an estate of known bad character. On the contrary, when once an estate has acquired the character of good faith and proper treatment of its tenantry, men of money and spirit will ever be anxious to gain a footing there. Besides, the character of an estate will ever involve that of its possessor: and, setting income at naught, it surely behoves a man of property to pay some attention to the character of his estates; for what can well add more to the permanent respectability of a family of rank or fortune, than having its estates occupied by a wealthy and respectable tenancy?

4669. *In a state of civilized society and property, one of the great arts of life is to teach character and interest to go hand in hand,* and on ordinary occasions to endeavour to turn every incident, as it fortuitously occurs, to their mutual advantage. If a tenant of capital and an improving spirit be found upon an estate, give him due encouragement, for the purposes already explained. On the contrary, if another is found to possess refractory habits, to swerve from his engagements, or to injure the lands in his occupation, it is but common prudence to take the first legal and fair opportunity of dismissing him, and supplying his place with another who is better qualified to fill it; not more with a view of rescuing his particular farm from further injury, and of making an example of him in terror to others of similar habits, than to preserve and heighten the character of the estate.

4670. *These remarks may be considered as applicable chiefly to small tenants,* or such as from ignorance and want of leases may be considered in a state of bondage. It ought never to be in the power of a landlord to make "an example of a tenant in terror to others;" it is enough if this power be left to the laws. A tenant who rents a farm on certain conditions, and fulfils them, is, in point of obligation, on an equality with his landlord; neither is obliged to the other; and while the one does not require those acts of kindness and liberality which Marshal inculcates, the other is not entitled to that submission and slavish deference so common among tenants at will, and indeed most others in England. It is justly observed by Brown (Treat. on Rur. Aff.) that the moral excitement, or degree of encouragement, given to the tenant for improving the ground put under his occupation, is regulated entirely by the terms or conditions of the lease under which he holds possession. If the conditions be liberal and judicious, and accommodated to the soil and situation of the land thereby denied to the tenant, all that is obligatory upon the proprietor is faithfully discharged. But when matters are otherwise, when the tenant possesses under a short lease, when the covenants or obligations are severe in the first instance and ultimately of little avail towards forwarding improvement, it may reasonably be inferred that the connection is improperly constituted, and that little benefit will thence follow either to the public or to the parties concerned. The proper view of a lease is, that it is merely a mercantile transaction reduced to writing, in which both parties are on an equal footing.

**Subsect. 2. Business of letting Farms.**

4671. *There are three methods of letting a farm:* putting it up to public auction, and taking the highest bidder for a tenant; receiving written proposals, and accepting the highest offer; and asking more rent for it than it is worth, haggling with different chapmen, and closing with him who promises to give the most money, without regard to his eligibility as a tenant. After a variety of obvious remarks, Marshal concludes, that "seeing in every situation, there is at all times a fair rental value, or market price of lands, as of their products, there appears to be only one rational, and eventually profitable, method of letting a farm; and this is, to fix the rent, and choose the tenant. In the choice of a tenant every body knows the requisite qualifications to be, capital, skill, industry, and character. The respective advantages of these qualities are amply developed in The Treatise on Landed Property.

**Subsect. 3. Different Species of Tenancy.**

4672. *The different holdings in use in Britain are at will, from year to year, for a term of years, or for a life or lives.*

4673. *The tenant holding at will, or until the customary notice be given by either party to the other, is without any legal contract, or written agreement; the only tie between the owner and the occupier being the custom of the estate or of the country in which it lies, and the common law of the land. This may be considered as the simple holding which succeeded the feudal or copyhold tenure; but which is now fast going into disuse.*

4674. *Holding from year to year,* under a written agreement, with specified covenants, is a more modern
usage, and becoming more and more prevalent in some parts of England, and among small tenants, even where a term of years was formerly granted. 4675. Leases for a term of years, as seven, fourteen, twenty-one, or a greater number of years, certainly; but without the power of assignment, unless with the consent of the lessor.

4676. Leases for lives; as, one, two, three, or more, without the power of assignment. In Britain, life leases of the whole farm are nearly granted. In Wales and Ireland there are still partly granted; but the being there settled according to the value of the land at the time of letting; as on granting a lease for a term. In the western extreme of England, what are termed life leases are still common; but they are rarely for life, and are only for lives, or a sale for life, or leases for, nearly the whole of the estimated sale value of the land, during the life term, is paid down at the time of purchase, the seller reserving only a quit rent, or annual acknowledgment.

4677. A lease for a term of years, or for two or more lives, can alone be favourable for the progress of agriculture. A farmer holding at will, or from year to year, may plough, sow, and reap; but he will, if a prudent man, be very careful not to make improvements, well knowing that the first effect would be a rise of rent or a notice to quit. Leases for a single life have the great disadvantage of uncertainty in duration, both as to landlord and tenant; and though the latter may insure a certain sum on his life for the benefit of his family, yet it was better that he should lay out that money in improving the farm. Leases on lives, renewable, are for all purposes of culture as good as freehold; but they have this disadvantage to a tenant, that they require a considerable part of his capital paid down, and a further draught on his capital on the falling in of any of the lives. Even the first of these payments would embarrass the great majority of professional farmers, and disable them from bestowing proper cultivation on the soil; but to a farmer with a surplus capital no description of lease can be better, as he lays out his surplus capital at the market rate of interest, and is, as it were, his own annuitant. To the landlord such leases cannot be advantageous; because, there being fewer who can compete for them, lands let on these conditions do not fetch their full price.

4678. The fundamental principle on which both the duration and conditions of leases are established is evidently this:—A agrees to lend to B a certain article for his use for an equivalent in money; but such is the nature of this article, that, in order to use it with advantage, B must possess it during a considerable time: he, therefore, requires a security from A to that effect; and A on his part requires a security from B that he will return the article at least in good as condition as when it was lent to him. The term of years for which the article is to be lent, and the precautions taken to insure its return without deterioration, are founded on experience, and vary according to the peculiar circumstances of lender and borrower. In general, however, this is obvious, that where the period of lending is not sufficient for profitable use, or the conditions required for ensuring the lender an undeteriorated return of the article unreasonable, the value of the loan or rent will be proportionally diminished. (Sup. Enc. Brit. art. Agr.)

4679. In recurring to what actually exists in the best cultivated districts, we shall quote the excellent observations of an experienced farmer and approved public writer:—"The general principle which should regulate the connection between landlord and tenant seems to be, that while the farm ought to be restored to the owner at the expiration of the tenant's interest, at least without deterioration, the tenant should be encouraged to render it as productive as possible during his possession. In both of these views, a lease for a term of years is scarcely less necessary for the landlord than for the tenant; and so much is the public interested in this measure, that it has been proposed by intelligent men, to impose a penal tax on the rent of lands held by tenants at will.

4680. That the value of the property is enhanced by the security which such a lease confers on the tenant will be put beyond all doubt, if the rents of two estates for half a century back are compared; the one occupied by tenants at will, and the other by tenants on leases for a moderate term, and where the soil and situation are nearly alike in every respect. If the comparison be made between two tracts originally very different in point of value, the advantages of leases will be still more striking: while that which is held by tenants at will remains nearly stationary, the other is gradually, yet effectually, improved, under the security of leases, by the tenants' capital; and, in no long period, the latter takes the lead of the former, both in the amount of produce, for which it yields to the proprietor, and in the quantity of produce which it furnishes for the general consumption. The higher rents and greater produce of some parts of Scotland than of many of the English counties, where the soil, climate, and markets are much more favourable, must be ascribed to the almost universal practice of holding leases in the former country, in a much purer or degree than in any of the causes which have been traced in the contrast. In Scotland, it is not more than a century ago, what are now the best cultivated districts of Scotland were very far behind the greater part of England; and, indeed, had made very little progress from the time of the feudal system. It is not fifty years since the farmers of Scotland, in the practice of guarding the security of the northern neighbour against the threat of the landlord, adopted an art, which was then very imperfectly known in their own country. But in several parts of England there has been little or no improvement since, while the southern counties of Scotland have uniformly advanced; and at present exhibit very generally, a happy contrast to their condition in the middle of the last century.

4681. In respect to farmers themselves, it cannot be necessary to point out the advantages of leases. It may be true, that, under the security of the honour of an English landlord, tenants at will have been continued in possession from generation to generation, and acquired wealth which it is impossible to wrest from them. But there are few individuals in any rank of life, who continue for a length of time to sacrifice their just claims on the altar of pure generosity. Something is always expected in return. A portion of revenue in this case is exchanged for power, and that power is displayed not only in the habitual degradation of the tenant, but in the control over them, which the landlord never fails to exert at the election of members of parliament, and on all other political emergencies. No prudent man will ever invest his fortune in the improvement of another person's property, unless, from the length of his lease, he has a reasonable prospect of being reimbursed.
PRACTICE of AGRICULTURE.

Part III.

with profit; and the servility which holding at will necessarily entails is altogether incompatible with that spirit of enterprise which belongs to an enlightened and independent mind.

Every measure which has a tendency to fetter the productive powers of the soil, must deeply affect the public at large; as well as depress one of the largest and most valuable classes. It is clearly the interest of the former, and therefore of the community, that the people of England may justly complain of the want of leases, as one of the principal causes which check the improvement of their own territory.

What ought to be the term of a lease can only be determined by a reference to the circumstances of each particular case. Land not naturally rich, or such as have already been brought to a high degree of fertility, requiring no great investment of capital, and returning all or nearly all the necessary outlay within the year, may be advantageously held upon short leases, such as perhaps give time for two, or at most three of the operations of crops or grass; or, in short, where the period of the landlord's interest is very short. The practice of England in this respect is extremely various, almost every term, from twenty years downwards, being found in different parts of it. In Scotland, by far the most common period is nineteen years, to which it was formerly the practice, in some places, to add the life of the tenant. In that country, even where the term is longer, the improvement of land is still conducted in periods of about twenty years, a sort of mysterious cycle, which seems to be no less a favourite with the courts of law than with landlords and farmers. Yet this term is somewhat inconvenient, as it can never correspond with any number of the recognized rotations of arable land.

A lease, for twenty years, has been maintained by several writers, is not sufficient to reimburse a tenant for any considerable improvements, and landlords have often been urged to agree to a much longer term, which, it is said, would not be less for their own interest than that of the tenant. This is a question which one only can not permit us to discuss; but, after viewing it in different lights, assisted by the experience of long leases in different parts of Scotland, we cannot help expressing some doubts of their utility, even so far only as it regards the parties themselves; and we are decidedly of opinion, that a greater produce will be brought to market, from any given extent of land held on successive leases of twenty years, for half a century, than if held on one lease of that duration, whether the term be specified, or indefinite as is the case of a lease for life. As a general mode of tenure, leases for lives seem to us very objectionable.

The great advantages of a lease are so well known in Scotland, that one of her best agricultural writers, himself a landed proprietor, has suggested a method of conferring on it the character of perpetuity, to such an extent as, he thinks, would give ample security to the tenant for every profitable improvement, and yet allowing the landlord the right of rescinding the lease and reducing the annual rent, on the expiration of every specified period. But the author of this plan (Lord Kaimies), in his ardent wishes for the advancement of agriculture, at that time in a very backward state in his native country, seems to have overlooked the defects of the system raised in the very nature of such a tenure; and the great advantage is the price of produce, and consequently in the rate of rents, since his lordship wrote, have long since put an end to the little advantage which his proposal excited. For a form of a lease on his plan, the reader may consult Bell's Treatise on Leases; and the objections to the plan itself are shortly stated in the supplement to the sixth edition of The Farmer, recently published.

Long leases granted upon condition of receiving an advance of rent at the end of a certain number of years have been granted: but objections of this kind, meant to apply to the circumstances of a distant period, are not to be draned as to do equal justice to the parties; and it ought not to be concealed, that, in every case of a very long lease, the chances are rather more unfavourable to the landlord than to the tenant. If the price of produce shall continue to rise as it has done, till very lately, for the last forty years, no improvements which a tenant can be expected to execute will compensate the landlord; and if he shall decline it, on the other hand, prices of corn become exhausted in a few years, and the landlords will necessarily revert to the proprietor, as has been the case in many instances. Hence a landlord, in agreeing to a long lease, can hardly ever assure himself that the obligations on the part of the tenant will be fully discharged throughout its whole term. Of the obligations he incurs himself may always be easily enforced. He runs the risk of great loss from a depression of money, but can look forward to very little benefit from a depression of produce, except for a few years at most. Of this advantage a generous man would seldom avail himself; and, indeed, in most instances, the advantage must be only imaginary, for it would be over-balanced by the deterioration of his property. (Stev. Encyc. Brit. art. Agr.)

There are various objections made to leases of nineteen or twenty-one years. Some of these are of a geographical nature; such as the inhabitance of the land, as long as it remains under corn, being purely-squeezed and saury under the nose of their landlord, &c. A greater objection has arisen from the depression of British currency during the last ten years of the eighteenth, and first ten of the nineteenth centuries. Various schemes have been suggested to counteract this evil; but the whole of these are liable to objections, and it may be doubted if it admits of any remedy, except a compromise between the parties.

Subsect. 4. Rent and Covenants of a Lease.

6488. To avert the evils of fixed money rents, and long leases, both to landlords and tenants, the best mode known at present is the old plan of corn rents. This plan was first revived in 1811, by a pamphlet published in Cupar, which attracted considerable attention, and has led to the adoption in various parts of Scotland, of a mixed mode of paying rents, partly in corn or the price of corn, and partly in money. In billy districts, wool, or the price of wool for an average of years, is sometimes fixed on instead of corn.

We shall quote from the same intelligent writer on the duration of leases, his sentiments on corn rents, and subjoin his observations on covenants.

6489. Though the most equitable mode of determining the duration of leases on land, would be to make it rise and fall with the price of corn; yet a rent paid in corn is liable to serious objections, and can seldom be a commercial arrangement. It necessarily bears heaviest on a tenant when he least able to discharge it. In very bad seasons, his crop may be so scanty, as scarcely to return seed and the expenses of cultivation, and the share which he ought to receive himself, as the profits of his capital, as well as the quantity allotted to the landlord, may not exist at all. Though, in this case, if he pays a money rent, his loss is small, or is only equal to the times of five or three of four years, according to the high price of such seasons. In less favourable years, which often occur in the variable climate of Britain, a corn rent would, in numerous instances, absorb nearly the whole free or disposable produce, as it is by no means uncommon to find the gross produce of even good land reduced from twenty to fifty per cent below an average in particular seasons. And it ought to be considered, in cases of this kind, that the landlord himself, that his income would thus be doubled or trebled, at a time when all other classes were suffering from scarcity and consequent dearth; while, in times of plenty and cheapness, he might find it difficult to make his expenses out of his stock. It would be, in the highest degree, of importance to both parties, that the amount of the rent should vary as little as possible from any unforeseen causes, though tenants in general would be perhaps the most injured by such fluctuations.
To abate these and other objections to a corn rent, and to do equal justice at all times to both landlord and tenant, a plan has been lately suggested for converting the corn into money, adopting for its price, not the price of the year for which the rent is payable, but the average price of a certain number of years. The rent, according to this plan, may be calculated every year, by omitting the first year’s rent, and then adding one year’s rent, and the average of the rent of the following year, and then be fixed according to a new average. Let us suppose the lease to be for twenty-one years, the average agreed on being seven years, and the first year’s rent, that is, the price of so many quarters of corn, the difference of the crop of the first and the price of the crop of the succeeding year. If it be meant to take a new average for the second and every succeeding year’s rent, all that is necessary is, to strike off the first of the seven years, adding the year for which the rent is payable, and so on during the period. If we add six years, slight as it is, the landlord would receive more rent without variation for the first seven years of the lease according to the average price of the seven years immediately preceding its commencement, and, at the end of this period, fixing a new rent, according to the average price of the seven years just expired, to continue for the next seven years. Then the new rent would be calculated, the quantity of corn the parties agreed to, the money payments would be equal to the average price of fourteen years of the lease itself, and of the seven years preceding it; and the price of the last seven years of the lease would be the fixed rent for the first seven years.

The landlord and tenant could not suffer, it has been thought, either from bad seasons, or any change in the value of the currency, should such a lease as this be extended to several periods of twenty-one years. The quantity of corn to be taken as rent, is the only point that would require to be settled at the commencement of each of those periods; and though this would no doubt be greater, according to the state of the lands at the time, yet it may be expected, that in the twenty-one years preceding, all the tenant’s judicial expenditure had been fully replaced. Instead of the twofold difficulty in fixing a rent for a long lease, arising from uncertainty as to the quantity of produce, which must depend on the state of improvement, and still more, perhaps, from the variations in the price of that produce; the latter objection is entirely removed by this plan; and in all cases where land is already brought to a high degree of fertility, the question about the quantity of produce may likewise be dispensed with, arising from uncertainty as to the amount of rent, as well as other difficulties which must necessarily attend it, would be as great, perhaps, as any advantages which it holds out to either of the parties. If it be said that this plan, at any rate, could not succeed, as no material change could ever be made to admit the impropriety of the contrivance. The first thing which must strike every practical man is, that corn is not the only produce of a farm, and in most parts of Britain, perhaps not the principal source from which rent is paid; and there is no authority for the record of the price of corn, such as there is of corn. This is not the place to enquire whether the price of corn regulates the price of all the other products of land, in a country whose statute books are full of duties, bounties, drawbacks, &c., to say nothing of its internal regulations; but it is sufficiently evident from the operations of this price on other crops, that price is not the criterion to be made as a just criterion for determining rent on a lease of this duration. Besides, in the progress of agriculture, new species or varieties of the cerealia themselves are established even in so short a period as twenty-one years. The price of one of them may be raised from that of the other, and it may be expected that the one will be a security for a full rent, for instance, would it give to a landlord, to make the rent payable according to the price of barley, when the tenant might find it more for his interest to cultivate some of the varieties of summer wheat, lately brought from the Continent? or, according to the price of a particular variety of oats, when the old varieties have been displaced by new ones; and all the same, the price of the districts, by the introduction of a new one, the potato-oat, which may not be more permanent than those that preceded it? There can be no impropriety, indeed, in adopting this plan, for ascertaining the rent of land always in tillage, but it would be idle to expect any important benefits from it, during such a lease as we have mentioned.

Book IV: RENTS AND COVENANTS OF LEASES. 767

The corn-rent, in the case of much longer leases, will no doubt diminish the evils which we think are insensible from them, but it cannot possibly reach some of the most considerable. Its utmost effect is to secure to the landlord a rent which shall in all time to come be an adequate rent, according to the state of the lands and the mode of cultivation known at the date of the lease. But it makes no provision that will apply to the enlargement of the gross produce from the future improvement of the land, or from the invention of new circumstances which may promote the kingdom’s agricultural circumstances. The objections just stated, in reference to a lease of twenty-one years, evidently apply much more forcibly to one of two or three times that length. Old corn-rents, though much higher at present than old money-rents, are seldom or never so high as the rents that could not now be obtained for the land, even under the most liberal terms, and if the landlord who wishes to enter more at length into this subject, may consult the most recent works on political economy, and especially M. McCall’s Principles. He will also find a paper on the subject, of some practical value, in the Quarterly Journal of Agriculture, vol. i. p. 156.

The most recent opinions on this subject are in favour of a money rent, or of a rent formed partly from the average prices of produce, and partly of comical, of which the greater part might be converted into the land rent. There seems, indeed, no essential reason why rents in agriculture should not be regulated on the same general principle as rents in commerce; and were it not for the extraordinary fluctuation that has taken place in the currency of the country within the last forty years, the principle of reasonable rent, and only the terms of the assessment, would in all probability have been adopted. The reader who wishes to enter more at length into this subject, may consult the most recent works on political economy, and especially M. McCall’s Principles. He will also find a paper on the subject, of some practical value, in the Quarterly Journal of Agriculture, vol. i. p. 156.

The terms of payment of rent differ a little in different districts and countries. Rents, in Scotland, are paid either previously to the first crop being reaped, when they are called fore-rents; or they are paid
PRACTICE IN RECEIVING RENTS.

After the reaping, when they are termed "back-rents." In England, it is believed that, with a few exceptions in the border counties, back-rents are not in use. The effect of these rents is, to afford a large credit to the tenant; it is assumed that his means of paying any year's rent are chiefly derived from the sale of the corn reaped that year, and he is allowed, according to custom, thus, if he enters at Whitsunday 1820, and at separation of crop 1829 from the ground, his first year's crop is that of 1830, and his first year's payment is usually made at Martimus 1830, and Whitsunday 1831. Were he to pay what is termed fore-rent, his first term's payment would be due at Martimus 1830, and his second crop would be the first crop after his first rent before his crop had been reaped. Wherever custom has established the system of back-rents, it should not be disturbed; by means of the credit afforded, tenants are enabled to take land with a smaller capital, and to expend those funds in the improvement of the farm, of which they must otherwise have been deprived. In Scotland this system is adopted with no hazard, since landlords have reason, a security by means of their lawful rights of hypothec, on the crop of the tenant. In the case of farms merely pastoral, indeed, the landlord's claims will not be well secured, because a tenant removing or leaving Whitsunday will have left no crop behind to answer for the rent; in farms of this nature, accordingly, it is stipulated that the tenant shall complete his year's rent before his crop had been reaped.

467. A lease for a term of years is not, in all cases, a sufficient encouragement to spirited cultivation; its covenants in respect to the management of the lands may be judicious; the tenant may be so strictly confined to a particular mode of culture, or a particular crop, as not to particularize the benefits of the better or the wastes of the worse; and the vicious state of agriculture never fails to introduce. Or, on the other hand, though this is much more rare, the tenant may be left so entirely at liberty, that either the necessity of his circumstances, during the currency of the lease, or his interest towards its expiration, may lead him to exhaust the soil, instead of rendering it more productive. When a lease therefore is either redundant, or deficient in this respect, where it either permits the lands to be deteriorated, or prevents their improvement; the connection between landlord and tenant is formed upon other views, and regulated by some other principles, than the general one on which we think it should be founded.

468. Restrictive covenants are always necessary to the security of the landlord, notwithstanding the high authority of Dr. Smith to the contrary, and in some cases beneficial to the tenant. Their expediency cannot well be questioned in those parts of the country where an improved system of agriculture has made it necessary for the landlord, as the owner of land, to assert and maintain his rights and title, and not adopt any easier or less offensive plan for the improvement of his property, and the ultimate advantages of his tenantry. Even in the best cultivated districts, while farms continue to be let to the highest rents, it is very difficult, or impossible, for a few restrictions upon covenants entered into. The tenant is too feeble a security for correct management, even during the earlier part of a lease; and in the latter part of it, it is thought to be his interest, in most cases, to exhaust the soil as much as possible, not only for the sake of immediate profit, but frequently in order to deter competitors, and thus to obtain a renewal of his lease. In a rent so high, and so less than the landlord's share, it is very wise. (Stap. Eng. Brit. art. Agr.)

In England the tenant is generally bound down by a mass of cumbersome and useless covenants, not only deriving him of the power of exercising all judgment, but often tying him to a course of practice. This is a general rule, but the exceptional cases are numerous. If, in the most part, the time and money, and indeed the possession, of it be intrusted to the tenant, he may, under these circumstances, and in this respect, he is too weak to exercise the security which he has promised. The improved knowledge, and the liberality of the age, have now expunged the most objectionable of these covenants; and throughout whole counties, almost the only restriction in reference to the course of crops is, that the tenant shall not take two culminating crops, ripening their seeds in close succession. This single stipulation, combined with the obligation to consume the straw upon the farm, and to apply to it all the manure made from its produce, is sufficient not only to protect the land from exhaustion, but to insure, in a great measure, its regular cultivation, in the case of both the cultivating parties. One of the most useful, and most simple, but the most important, not in prohibitions, but in practical rules, as such practices and such crops as experience has sanctioned. The improved knowledge, and the liberal views of the relations, have now expunged the most objectionable of these covenants; and throughout whole counties, almost the only restriction in reference to the course of crops is, that the tenant shall not take two culminating crops, ripening their seeds in close succession. This single stipulation, combined with the obligation to consume the straw upon the farm, and to apply to it all the manure made from its produce, is sufficient not only to protect the land from exhaustion, but to insure, in a great measure, its regular cultivation, in the case of both the cultivating parties.

469. With tenants at will, and such as hold on short leases, restrictive covenants are more necessary than with tenants on leases of nineteen or twenty years; but in many instances, they are too numerous and complicated, and sometimes even inconsistent with the best courses of modern husbandry. The great error lies in prescribing rules by which a tenant is positively required to act, not in prohibiting such practices and such crops as experience has sanctioned. The improved knowledge, and the liberality of the age, have now expunged the most objectionable of these covenants; and throughout whole counties, almost the only restriction in reference to the course of crops is, that the tenant shall not take two culminating crops, ripening their seeds in close succession. This single stipulation, combined with the obligation to consume the straw upon the farm, and to apply to it all the manure made from its produce, is sufficient not only to protect the land from exhaustion, but to insure, in a great measure, its regular cultivation, in the case of both the cultivating parties. One of the most useful, and most simple, but the most important, not in prohibitions, but in practical rules, as such practices and such crops as experience has sanctioned. The improved knowledge, and the liberal views of the relations, have now expunged the most objectionable of these covenants; and throughout whole counties, almost the only restriction in reference to the course of crops is, that the tenant shall not take two culminating crops, ripening their seeds in close succession. This single stipulation, combined with the obligation to consume the straw upon the farm, and to apply to it all the manure made from its produce, is sufficient not only to protect the land from exhaustion, but to insure, in a great measure, its regular cultivation, in the case of both the cultivating parties.

The only other necessary covenant, when the soil is naturally too weak for carrying annual crops without intermission, is, that a certain portion of the land shall be always in grass. According to the extent of this, will be the interval between the succession of corn crops on the same field; if it be agreed that half an acre shall be grass, the same land may be under grass on one field in six years. In this case, not more than two sixths being in corn, one sixth in green crops or fallow, and three sixths in clover or grasses, it becomes almost impossible to exhaust any soil at all fitted for tillage. For, indeed, if a field is not gradually improved, and if it be not regularly cleared, it is sufficiently evident, that other covenants are necessary in particular circumstances; such as permission to dispose of straw, hay, and other crops from which manure is made, when a quantity of manure cannot be used, or when there is need of manure, or when there is need of manure; and a prohibition against converting rich old grazing lands or meadows into corn lands. In this place we speak only of general rules, such as are applicable to, perhaps, nine tenths of all the arable land of Britain, and such as are actually observed in our best cultivated counties.

470. With leases of less than four years of a lease, the same covenants are generally sufficient, only they require to be applied with more precision. Instead of taking for granted, that the proportion of the farm that cannot be under corn, will be properly cultivated, from the tenant's regard to his own interest, it becomes necessary to fix, at the beginning of the term, the proportion of the land to be left fallow, or which the tenant, upon a new lease, to carry on the cultivation of the lands, as if the former lease had not terminated, and the usual stipulations, which are necessary to be included in the lease, as it with the lease, and in the course of the lease, both of the landlord, and in the case of the tenant, and in the course of the lease, and the cases of the tenant.

471. With respect to the form of a lease, as no one form would suit every district, nothing specific can be laid down with advantage. The Lawyers of every estate have particular forms, and it is easy for them, in cases of this kind, to alter, and, if necessary, to provide, to oblige the lessee to comply with these restrictions, and substitute such, as may be deemed best for the estate, or in harmony with the progress of the age. (Sup. Encyc. Brit. art. Agr.)

SUBSECTION 5. RECEIVING RENTS.

472. The business of receiving the rents and profits of a landed estate, simple as it may seem, is subject to analysis, and entitled to consideration. Indeed, on large properties, on which not farm rents only, but various other profits, are to be received, as cottage rents, tithe compositions, chief rents, and, perhaps, quit rents of copyhold lands; the business becomes so complex as to require to be methodized and simplified, in order to obtain the requisite facility and despatch. This is generally best effected by appointing
distinct days, or distinct parts of the day, for each receipt, so that the different tenants and suitors may know their hours of attendance.

4703. The business of holding manor courts depends on whether they are held of right, or merely by custom. If the copyhold tenure is so far worn out in any manor, that there are not two ancient or feudal tenants remaining within it, the court has lost its legal power; it cannot by right take cognizance of crimes, nor enforce amercements. Nevertheless, manorial courts have their uses, in regulating farm roads, driftways, and water-courses, and in preventing nuisances of different kinds within a manor; and it is generally right to preserve the custom of holding them for these purposes.

4704. Where copyhold courts remain in force, and where legal forms are to be observed, a law "steward of the manor" is proper to hold them. It is not necessary, however, that courts of this kind should interfere with the receipt of farm rents; or that a business of this nature should in any way clash with the general receivership of the estate. Employ an attorney to hold courts, as a surveyor to arbitrate disputes, or an engineer to plan works of improvement.

4705. The propriety of having fixed days for receiving the rents of farms is evident; and some consideration is required to determine on the season of the year for holding them, so as not to oblige the farmer to forced sales of his produce. In England and Ireland, farm rents are generally due at Lady-day and Michaelmas, and in Scotland at Candlemas and Lammas. But the proper times of paying them depend on the marketable produce of an estate, and on the season of the year at which it goes in common course, and with the best advantage, to market. A tenant should never be forced to sell his produce with disadvantage; nor, when he has received his money for it, ought he to be at a loss for an opportunity of discharging his debt to his landlord. On corn-farm estates, or those whose lands are kept in a state of mixed cultivation, which comprise the great mass of farm lands in this kingdom, Michaelmas may be considered as one of the worst times of the year, at which to call upon tenants for their rents. It is at the close (or, in the northern provinces, perhaps at the height) of harvest, when the farmers' pockets are drained by extra labour, and when they have not yet had time to thresh out their crops to replenish them; nor is the summer's grass at that season yet consumed, nor off-going stock, perhaps, yet ready for market. In Norfolk, Marshal found the end of February, or beginning of March, a very fit time to pay the half year's rent due at Michaelmas; and June for paying those due at Ladyday. In some districts of the north it used to be the custom not to demand the first half year's rent, till the tenant was a year in his farm, by which means he had the use during his lease of nearly a year's rent in addition to his actual capital. But farmers there being now considered as possessed of more wealth than formerly, the first half year's rent of the lease is paid nine months after possession, and the last half year's rent of the term on or immediately before its expiration.

4706. The proper days for receiving rents are to be determined by the local circumstances of an estate and the district in which it lies; more especially by the fairs of the neighbourhood at that season, and by other stated times at which the tenants are accustomed, in conformity with the practice of the country, to receive for their dairy produce or other articles delivered in to dealers; and should be fixed immediately after these days of embursement.

4707. On the subject of arrears, a good deal has been said by Marshal; but it is one of those which may very safely be left to the good sense and discretion of the proprietor or his manager.

Sect. III. Keeping and Auditing Accounts.

4708. Clearness and brevity constitute the excellence of accounts, and these excellencies are only to be obtained by simplicity of method. Where lands lie in detached estates so as to require different receivers, a separate account is necessarily required for each receivership; but to preserve this simplicity and clearness, it is necessary that the several sets should be in precisely the same form.

4709. The groundwork of the accounts peculiar to a landed estate is the rent-roll: from this receiving rentals are to be taken, and with these and the miscellaneous receipts and disbursements incident to the estate, an account current is to be annually made out.

4710. In the receiving rental the particulars which a receiver wants to see at one view, when receiving the rents of an estate under judicious management, where rents are regularly received, and where occupiers pay taxes and do ordinary repairs, are few; the name of the farm, the name of the tenant, and the amount of his half year's rent only are required: but upon an estate, on which arrears are suffered to remain, and on which matters of account are liable to take place, a greater number of particulars are necessary; as the name of the farm, of the tenant, his arrears, his half year's rent, any other charge
against him, any allowance to be made him, and the nett sum receivable, leaving a
blank for the sum received and another for the arrear left.

4711. Accounts current are required to be delivered in annually by the acting manager,
who ought generally to be the receiver. If the current receipts and disbursements are
numerous, as where extensive improvements are going on, and woods, mines, quarries, &c.,
in hand, such accounts may be given in monthly, which will show the progress of the
several concerns, and simplify the business at the end of the year.

4712. On the best managed estates it is usual, besides the books which have been
mentioned, to keep a ledger; opening separate accounts for farm lands, woods, mines,
quarries, waters, houses and their appurtenances, public works, &c.; and where a pro-
prietor has several detached estates, besides such accounts being kept on each, one master
ledger contains accounts for the whole property. This, indeed, is nothing but an ob-
vious application of mercantile book-keeping to territorial property, the advantages
of which cannot but be as great in the one case as in the other.

4713. In auditing estate accounts, the rent accounts are to be checked with the arrears
of the preceding year; the column of rents with the rent-roll, corrected up to the last
term of entry in order to comprise the fresh lettings; and the columns of account with
the particulars, those of allowances being signed by the respective tenants.

4714. The monthly accounts of receipts and disbursements, as well as the annual pay-
ments, are to be compared with vouchers. The receipts are checked by deeds of sale,
contracts, and other written agreements, the awards of referees, or the estimates of sur-
veyors, the market prices of produce, &c.; the receiver, in every case, identifying the
person from whom each sum was received. Each disbursement requires a direct and
sufficient voucher, endorsed and numbered, with a corresponding number affixed to the
charge in the account, so that they may be readily compared.

4715. The most essential part of the office of an auditor is that of entering into the
merits of each receipt and payment; and considering whether the charges correspond
with the purposes for which they are made; and whether the several sums received are
adequate to the respective matters disposed of; by these means detecting, and thence-
forward preventing, imposition and connivance. This, however, is an office which no
one but a proprietor, or other person, who has been conversant with the transactions that
have taken place upon the estate, and who has a competent knowledge of rural concerns,
can properly perform. It may therefore be right to repeat, that if a proprietor has not yet
acquired a competent knowledge of his own territorial concerns, to form an adequate
judgment of the different entries in his manager's account, he should call in the assistance
of those who are conversant in rural affairs, to enable him to judge of any particular parts
that may seem to require it; and should not set his hand to an account which he does
not clearly understand, nor authorise another to sign it, who may have less knowledge
than himself of its merits.

BOOK V.

SELECTION, HIKING, AND STOCKING OF FARMS.

4716. Farms or lands let out to men who cultivate it as a business or profession exist in
all highly civilized countries. Sometimes the farmer or tenant pays to the proprietor or
landlord a proportion of the produce, determined yearly, or as the crops ripen; and
sometimes he pays a fixed quantity of produce, or labour, or money, or part of each of
these. In Britain, where farming, as a profession, is carried to a higher degree of per-
fection than in any other country, the connection between landlord and tenant is regularly
defined by particular agreements and general laws; and the latter, on entering on a farm,
engages to pay a fixed sum for its use for a certain number of years. This sum is fixed
according to the estimated value of the land; but being fixed, and for a certain time,
it admits of no abatement in proportion to the quantity or value of the produce, as in the
proportional or metayer system general in most countries (265. and 596.); and hence
the necessity of a farmer maturely considering every circumstance connected with a farm
before he becomes its tenant. The subjects of consideration form the business of this
Book, and naturally divide themselves into such as relate to the farm, to the farmer, and
to the landlord. Some of the subjects, being treated of in the preceding Book, will be
but slightly noticed, though, as connected with the object of the present, they could not be
altogether omitted.
Circumstances of a Farm necessary to be considered by a proposed Tenant.

4717. Whoever intends to become a professional or rent-paying farmer will, in searching for a farm, find it necessary to attend to a great variety of considerations. Those of the greatest importance may be included under climate, soil, and subsoil, character of surface, topographical position, extent, buildings, roads, fields, tenure, rent, and outgoings. In The Code of Agriculture, a more valuable collection of facts as to these points is brought together than in any other work, and from it, therefore, we shall select the greater part of the following sections.

Sect. I. Climate, in respect to Farming Lands.

4718. The climate of a farm is one of the circumstances over which human art has less control than over any other; and a farmer who has but a temporary interest in his possession may be considered incapable of exercising any influence over it. He may improve the soil and subsoil by draining and culture; and the buildings, roads, and fences by additions and alterations; but it is for the landlord to attempt improving the climate by planting, and for a future generation to enjoy the effects.

4719. Sufficient attention, it is said in The Code of Agriculture, “is rarely paid by the farmer to the nature of the climate in which his operations are carried on. Unless the system he adopts be calculated for the weather his crops are likely to experience, every exertion will often terminate in disappointment. The system that is proper for warm and dry situations is not suitable for cold and wet ones, and in a bleak and backward climate, the nature of the soil ought not only to be attended to, but the utmost care ought to be paid to the early sowing of the earliest varieties of seed. Even the species of stock to be bred or kept on a farm should, in a great measure, be regulated by the climate. Hence, this is a subject which the diligent farmer will invariably study with the greatest solicitude. Climate and soil, Curwen justly remarks, are, above all other considerations, those which the farmer ought constantly to keep in view.” (Report to the Workington Society).

4720. In considering the climate of a country, the following points are of peculiar importance: — Its general character, and the means of its improvement; its local heat; the light it furnishes; the quantity of its moisture; the prevailing winds; its position, whether maritime or inland; the regularity of the seasons; the phenomena to which it is liable; the productions best suited to it; the expenses it may occasion in cultivation; and its suitableness for the introduction of exotic plants and animals.

4721. The general character of a climate not only depends on position or latitude, but likewise on the elevation of a country above the level of the sea; its general aspect; the vicinity to mountains, forests, bogs, marshes, lakes, and seas; the nature of the soil and subsoil, and the power which the former possesses of retaining heat and moisture; the direction of the winds; the length of time the sun continues above the horizon; the difference of temperature between the day and the night; the length of time the sky remains covered with clouds; the frequency of storms; the mean climate of the sea-coast; and, in general, the character of dry surface in the neighbourhood. The result of these particular combined form what may be called the general character of climate. Some of the causes of an unfavourable climate cannot be remedied by any human effort; in other cases, art may effect much; but that art is generally so situated as to seldom undertake, unless with a very long lease. Ameliorations of this sort, therefore, belong to the landlord.

4722. The importance of heat, as a stimulus to vegetation, cannot be doubted. It is at a certain degree of temperature that plants commence their stages of growth when the temperature falls below it. There are, comparatively speaking, but few plants calculated for very cold countries, and these are seldom valuable; whereas, in warm and temperate regions, the variety is great, and their value unquestionable. Indeed, such is the effect of cold, that, while the thermometer is below sixty degrees of heat, the strongest plants become torpid, and remain in that state while it continues; but, when the warming effect of spring, and strengthened by the heat of summer, they acquire fresh life and vigour, and are thus better enabled to withstand the rigours of the succeeding winter.

4723. An increased temperature, when not carried to excess, will augment the quantity of nutritious matter in a plant, or improve the quality of fruit grown under its influence. Thus, English barley, of equal weight, is more valuable than the Scotch, because, from growing in a warmer climate, and enjoying the advantage of a greater quantity of heat and light, it is more fully ripened; it there acquires more saccharine matter, and produces a greater quantity of spirits, or of malt liquor. It is also proved, by the experiments of Sir Humphry Davy, that wheat, ripened in a more regular and warmer climate, contains more of that valuable article called gluten, than the same species of grain when raised in England.

4724. The average of the temperature, however, of so much importance to the growth of plants, as its duration, and its steadiness at a certain degree, during the season when the grain is ripening. This gives the uniform climates of the Continent a great advantage over our variable seasons, in the production of the more delicate sorts of fruit; which, in this island, are often injured by the frosts in spring, and seldom grown in a northern climate, where the greatest summer heat is both unsteady and of short duration.

4725. The quantity of solar light which a climate furnishes, is likewise an important object of enquiry. Light, in the east, increaseth the proportion of starch or farina; to complete the formation of oils in plants; and to give to fruits their proper colour and flavour. It has also the effect of augmenting saccharine matter, inasmuch that those sugar-canes which are exposed to the sun have more of that important ingredient than when they grow under shade. Nor ought the observation to be omitted, that darkness and light have effects directly opposite on various vegetables. Darkness favours the length of the growth, by keeping up the pliancy of their parts; light consolidates them, and steps growth, by favouring maturation. Hence, in the northernmost regions, plants go through most of their stages of growth at a time when the sun no longer quits the horizon; and the light, of which they thus experience the unremitting effect, hardens them before they have time to lengthen. Their growth is therefore quick, but of short duration. They are robust, but undersized. (Murr. It has been remarked also, that a soil, not reten-
tive, will be more productive in a wet climate than in a dry one. Hence, in the western coasts of England, as in Lancashire, where the quantity of rain that falls annually varies from forty to sixty inches, a sthail
and sandy soil is much more productive than the same species of soil in the eastern districts. In wet climates, also, even wheat and beans will require a less coherent and absorbent soil than in drier situations. At the same time, weather moderately dry is the most favourable to a great produce of corn; and the blossoms of wheat, in part
icular, set best if no rain falls in the flowering season.

472. The quantity of rain that falls annually in any country is a very inferior consideration, when compared with that of the general and equitable distribution of that quantity throughout the several days and months of the year. A great quantity, at the same time, is rather hurtful than beneficial; whereas those moderate, but golden showers, which regularly fall on a soil calculated to receive them, are real souces of fertility. It is by this means that the character of the soil, whether wet or dry, is chiefly determined, and the operations of agriculture are principally influenced.

473. The utility of a moist atmosphere, with a view to vegetation, is, in some respects, peculiarly remarkable. Thus, in wet climates, as on the western coasts of England, the leaves of grass and wood are in a greater degree than in milder ones; and in the former, should be sown much earlier than in the latter.

474. The disadvantages of a wet climate to a farmer, more especially if accompanied with a retentive soil, are very great. It is calculated, that in the richest district in Scotland, the Carse of Gowrie, there are only about twenty weeks in the year fit for ploughing; whereas in several parts of England, they have thirty weeks, and in many cases more, during which this essential operation can be performed. Hence, it is that the much more expensive in the centre districts of Europe, than in the southern districts of the German Ocean. The latter are loaded with the vapours of the Atlantic, and often, from excess of moisture, are rendered prejudicial.

475. The prevailing winds have a great influence on the character of a climate. When they pass over a large expanse of water, they are usually of a warmer or higher temperature than those rising over land; they are kept back from descending to lower countries. The power of evaporation is less in seas than in land, and it is not surprising, that the climate of Moscow, which is situated somewhat farther south than Edinburgh, experiences winters much more severe. Another effect of a maritime position is, that strong winds which blow from the sea are naturally more moist than those which blow from the continent. Hence, when they hit the land, they reflect the exposed moisture of the sea, and become an object to suit the produce to them; and to form fences, enclosures, and plantations accordingly.

476. The importunities of the natural position is also of much importance. The relative position of the neighboring hills occasions a material difference of climate, exposing some districts to great severity of weather, and protecting others from that disadvantage, greatly promoting their fertility.

477. In many countries the seasons are regular. In others, as in Great Britain, they are extremely variable, and often change, in the space of a few hours, from dry to moist, from hot to cold, from clear to cloudy weather. All the irregularities of climate, however uncomfortable, are often favourable to vegetation, and compensated by the advantages they produce. It is not in countries where the seasons of heat and cold, wind and rain, are periodic, or where those bare and unvaried climates, that manufacture and agriculture can be cultivated with success.

478. The climate of a country is likewise affected by atmospheric and natural phenomena; by earthquakes, volcanos, violent thunder storms, lightning, hail storms in summer, early frosts, whirlwinds and hurricanes, water-spouts; and by the phases of the atmosphere, so frequently to be seen in northern, and sometimes even in southern, regions; but these are very much more rarely attended with permanent evil. It is true, that the heat of spring is injurious to the blossoms of fruit trees; and autumnal frosts creep along the banks of rivers, destroying the corn in the flowering season, and blasting the stems of potatoes in low situations. Winter frosts are ultimately rather favourable to vegetation; and snow, particularly when it covers the ground for the first time, and gradually decreases, is beneficial to vegetation;

479. By a favourable climate, also, the most barren spots, which in a cold country
must remain complete, waste, in a warm one may be rendered productive. Thus, where the climate is adapted to the culture of the vine, rocks, which in Great Britain, and in colder countries, would in general be of little or no worth, in the southern provinces of France, is much in demandable, and valuable produce as the cultivated land in their natives, which is observed on its yielding, in perfection and abundance, the necessary of life, or those which constitute the principal articles of food for man, and for the domestic animals kept for his use. In this point of view, a meadow is by the same means as in warmer climates, the more generally cultivated than the vineyard, though the one may be situated in a cold and variable climate, and the other in a country celebrated both for its regularity and warmth of temperature.

472. Even the nature of the soil and the nature of the climate depend upon the climate. Thus, in many elevated parts, both of England and Scotland, wheat cannot be grown to advantage, and in some of the high-lying districts of the latter, it has never been attempted. In several of the northern counties, it has been found necessary to sow, instead of the two-rowed barley, the inferior sort called hear or big; and oats, from the hardness of the soil, are certain and reliable, than four or more crops, than any other; while in humid districts peas or beans cannot be safely cultivated, from the periodic wetness of the autumn. On the whole, without great attention to the nature of the climate, no profitable system can be worked, by any occupier of land.

473. An inferior climate greatly augments the expenses of cultivation; because a number of horses are required for labour during the short period of the year, when the weather will admit of it, which, at other seasons, are a useless burden upon the farm. When to this are joined an uneven surface and an inferior quality of soil, arable land is of little value, and yields but a trifling rent.

474. Exotic plants or animals can only be naturalised in climates with success by paying attention to that wherewith they were brought, and by endeavouring either to render the one as similar to the other as circumstances will admit of, or to counteract, by judicious managements, the deficiencies of the new one.

475. In order to ascertain the nature of a climate, the farmer, in modern times, has many advantages which his predecessors wished for in vain. The progress of science has given rise to many new instruments, which ascertain natural phenomena with a considerable degree of accuracy. It may still be proper to mention the thermometer, from the use of which it seems, that we are not to despise the heat and cold, and the weather; but the vane now points out the quarters whereby the winds blow, with all their variations; the barometer often enables us to foretell the state of the weather that may be expected; the thermometer augments our knowledge of the degree of moisture in the atmosphere, the degree of heat or cold; and the quantity of rain that has fallen during any given period; and, by keeping exact registers of all these particulars, much useful information may be derived. The influence of different degrees of temperature and humidity, occurring at different periods, may likewise be observed, by comparing the leasling, flowering, and fruiting periods of the most useful trees and plants, in different seasons, or the period when the several crops of grain are sown and reaped each year.

Sect. II. Soil in respect to farming Lands.

476. The necessity of paying attention to the nature and quality of the soil need not be dwelt upon. By ascertaining the qualities it possesses, or by removing its defects, the profits of a farmer may be greatly increased. He must, in general, regulate his measures accordingly, in regard to the rent he is to offer; the capital he is to lay out; the stock he is to keep; the crops he is to raise; and the improvements he is to execute. Indeed, such is the importance of the soil, and the necessity of adapting his system to its peculiar properties, that no general system of cultivation can be laid down, unless all the circumstances regarding the nature and situation of the soil and subsoil be known; and such is the force of habit, that it rarely happens that a farmer who has been long accustomed to one species of soil will be equally successful in the management of another. From inattention to the nature of soils, many foolish, fruitless, and expensive attempts have been made to introduce different kinds of plants, not at all suited to them; and manures have often been improperly applied. This ignorance has likewise prevented many from employing the means of improvement, though the expense was trifling, and within their reach. From ignorance also of the means calculated for the proper cultivation of the different soils, many unsuccessful and pernicious practices have been adopted.

Soils may be considered under the following general heads:— Sandy; gravelly; clayey; stony; chalky; peaty; alluvid; and loamy, or that species of artificial soil into which the others are generally brought by the effects of manure, and of earthly applications, in the course of long cultivation.

477. Though sandy soils are not naturally valuable, yet being easily cultivated, and well calculated for sheep, that most profitable species of stock, they are often farmed with considerable advantage; and when of a good quality, and under a regular course of husbandry, they are invaluable. They are easily worked, and at all seasons; they are cultivated at a moderate expense; are not so liable to injury from the vicissitudes of the weather; and in general they are deep and retentive of moisture, which secures excellent crops of grass, and keeps the liveliest farmers, their cattle, and their horses, well fed. They are well adapted to the growth of carrots, barley, rye, buck-wheat, peas, clover, stainton, and other grasses. This species of soil, in general, has not strength enough for the production of Spanish turnips, beans, wheat, flax, or hemp, in any degree of perfection, without much improvement in its texture, the addition of great quantities of enriching materials. When such is the case, however, the farmer, for any other purpose, will, under stainton, produce, after the first year, about two tons per acre of excellent hay, for several years; with an after-grass, extremely valuable for weaning and keeping lambs. Parts of which it supports, are hard in substance, and rounded in form. Gravelly soils are easily cultivated, for the annual and vegetable matters they contain, not being thoroughly incorporated with the earthly constituent parts of the soil (which are seldom sufficiently abundant for that purpose), are more liable to be decomposed by the action of the atmosphere, and carried off by water.
474. A gravelly soil, free from stagnant water, gives such an additional warmth to the climate, that vegetation is nearly a fortnight earlier than where other soils predominate. About Dartford and Blackheath, in Kent, such soils produce early green peas, winter tares, rye, autumnal peas, and occasionally belong to great perfection.

475. Gravelly soils, in a wet climate, answer well for potatoes; in Cornwall, in a Sheltered situation, with a command of sea-sand, and of sea-weed, they raise two crops of potatoes in the same year.

476. Light, gravelly soils, and those subsoils, are very unfriendly to vegetation; and are better calculated for wood than for arable culture.

477. The stony, shaley, or stone-breach soils of Gloucestershire, and the Midland counties of England, are much mixed with gravel, and are usually frequented by hail; and gravelly soil, or calcareous loam, in their constitution more than gravelly soil, and are therefore generally preferable.

478. A clayey soil is often of so adhesive a nature that it will hold water like a dish. In a dry summer, the plough turns it up in green clods, scarcely to be broken or separated by the heaviest roller. It requires, therefore, less labour in producing a first furrow, and a self for preparing the land for justice, than for gravelly soil, which can be cultivated when in a particular state, and in favourable weather. Though it will yield great crops under a proper system of management, yet, being cultivated at a heavy expense, requiring stronger instruments and laborious toil, is seldom found to reach much profit, unless when occupied by a judicious and attentive farmer. The best management of clay soil is that of the Lothians. There they are found well calculated for growing crops of beans, wheat, oats, clover, and winter tares: but are not adapted for barley, unless immediately after a fallow; nor for potatoes, unless under very peculiar management. In regard to turnips, they do not usually thrive so well in clays, as in soils which are more free and open: but it is now ascertained, that the Swedish, and above all the yellow, turnip may be raised in them with advantage; that the quality is superior; that if they are taken up early, the soil is not injured; and that there is no difficulty in preserving them. Clays become good meadow-lands, and answer well for hay, or soiling, when in grass; but from their aptitude to be poached, they are, in general, unfit to be fed by heavy cattle in wet weather. In dry seasons the after-grass may be used to feed neat cattle till October, and sheep till March. A stiff clay, when not cold or wet, with a strong marl under it, is preferred in Cheshire, Lancashire, and Yorkshire for the hay crop.

479. On reclaimed peat-bogs, oats, rye, beans, potatoes, turnips, carrots, cloe-seed, and white and red clover, may be cultivated. Wheat and barley have succeeded on such lands, after they have been supplied with a covering of the sloughy grass; and the forage is superior to that grown on any soil adapted to that description of soil in a warm climate. In Leicestershire, and other counties, they have great tracts of meadow-land; these are, in many instances, the sites of lakes filled up, and the soil is composed of peat and sediment; the peat originally formed by aquatic vegetation, and the sediment brought down from the fells of the county. This soil is admirably calculated for husbandry; and which has always been conducted by wise management, during a number of years, have been brought to a considerable degree of fertility as grazing land, and which are so useful to sheep in the winter season. A chalky soil that has been in tillage permits water to pass through it so freely in winter, and is so pervious to the sun's rays in summer, that it is the worst tillage for it; make it good meadow-lands, and give it a surface. Hence, in the western counties of England, several thousands of acres of this soil, though not ploughed for thirty years, have scarcely any grass of tolerable quality upon them, and are literally worthless for nothing. Such soils ought to be laid down with sanfton.

480. Leaky soils principally consist of calcareous matter mixed with various substances, in greater or less proportions. Where clayey or earthy substances are to be found in such soils in considerable quantities, the composition is heavy and productive; where sand or gravel abounds, it is light, and rather unfertile. The crops chiefly cultivated on chalky soils are peas, turnips, barley, clover, and wheat; and, however much the soil is exhausted, it will still produce the same crops. Leaky soils are in general better for tillage than for grazing; for, without the plough, the peculiar advantages derived from this soil by sanfton could not be obtained. The plough, however, ought not to be carried so deeply as on chalky soils in England; and every attention to its management during a number of years, have been brought to a considerable degree of fertility as grazing land, and which are so useful to sheep in the winter season. A chalky soil that has been in tillage permits water to pass through it so freely in winter, and is so pervious to the sun's rays in summer, that it is the worst tillage for it; makes it good meadow-lands, and give it a surface. Hence, in the western counties of England, several thousands of acres of this soil, though not ploughed for thirty years, have scarcely any grass of tolerable quality upon them, and are literally worthless for nothing. Such soils ought to be laid down with sanfton.

481. Leaky soils are of two sorts; one derived from the sediment of fresh, and the other from that of salt water. Along the sides of rivers, and other considerable streams, water-formed soils are to be met with, consisting of the decomposed matter of decayed vegetables, with the sediment of streams. They are very fertile and injurious to the injured, and apt to be washed away by the current of the gravel. They are commonly employed as meadows, from the hazard of crops of grain being injured or carried off by floods.

482. Alluvial soils, arising from the operations of salt water, called salt marshes in England, cresses in Scotland, and polders in Holland and Flanders, are composed of the finest parts of natural clay, washed off by running water, and deposited on flat ground, on the shores of estuaries, where they are formed by the reflux of the tide, and enriched with marine productions. They generally have a rich level surface, and being deep in the staple, they are well adapted for the culture of the most valuable crops. Hence wheat, barley, oats, and clover are all of them productive on this species of soil; which is likewise peculiarly well calculated for beans, as the tap root pushes vigorously through it, and finds its nourishment at a great depth. From the great mass of excellent soil, the fertility of these lands is nearly inexhaustible; but, from their low and damp situations, they are not easily managed. Lime, in considerable quantities, is found to answer well upon this species of soil.

483. The term loamy soil is applied to such as are moderately cohesive, less tenacious than clay, and more than sandy loams. Loams are the most desirable of all soils to occupy. They are friable; can in general be cultivated at almost any season of the year; are ploughed with greater facility, and less strength than clay; bear better the vicissitudes of the seasons; and seldom require any change in the rotation of crops. Although peculiarly well calculated for the culture of vegetables, not only without injury, but generally with benefit, from grass to tillage, and from tillage to grass.

484. As to the comparative value of soil, it has been justly remarked, that too much can hardly be paid for a good soil, and that even a low rent will not make a poor one profitable. The labour of cultivating a rich and a poor soil is nearly the same; while the latter requires more manuring and consequently is more expensive. Poor soils, at the same time, may have such a command of resting manures, as lime or marl, or even of temporary sorts, like sea-weed, or the refuse of fish, as may render them profitable to cultivate. It is a wise maxim in husbandry, that the soil, like the cattle by which it is cultivated, should always be kept up in good condition, and never suffered to fall below the work it may be expected to perform.

Sect. 111. Subsoil relatively to the Choice of a Farm.

4760. On the nature of the under-stratum depends much of the value of the surface soil. On various accounts its properties merit particular attention. By examining the
subsoil, information may be obtained in regard to the soil itself; for the materials of the latter are often similar to those which enter largely into the composition of the former, though the substances in the soil are necessarily altered, by various mixtures, in the course of cultivation. The subsoil may be of use to the soil, by supplying its deficiencies and correcting its defects. The hazard and expense of cultivating the surface are often considerably augmented by defects in the under-stratum, but which, in some cases, may be remedied. Disorders in the roots of plants are generally owing to a wet or noxious sub-soil. Subsoils are retentive or porous.

4761. Retentive subsoils consist of clay, or marl, or of stone beds of various kinds. A retentive clayey subsoil is in general found to be highly injurious. The surface soil is soaked with water, is ploughed with difficulty, and is usually in a bad condition for the exertion of its vegetative powers, until the cold sluggish moisture of the winter be exhausted. By the water being retained in the upper soil, the putrefactive process is interrupted, and manures are restrained from operating, consequently the plants make but little growth. Hence, its grain is of inferior quality, and when in grass its herbage is coarse.

4762. A stony subsoil, when in a position approaching to the horizontal, is in general prejudicial, and, if the surface-soil be thin, usually occasions barrenness, unless the rock should be limestone; and then the soil, though thin, may be rendered healthy pasturage and, by favourable seasons, will feed a heavy stock. They will also produce good crops of corn, though subject to the wire-worm. Also produce good crops of corn, though subject to the wire-worm.

4763. A porous subsoil is uniformly attended with this advantage, that by its means all superfluous moisture may be absorbed. Below clay, and all the variety of loams, an open subsoil is particularly desirable. It is favourable to all the operations of husbandry; it tends to correct the imperfections of too great a degree of absorbent power in the soil above; it promotes the beneficial effects of manures; it contributes to the preservation and growth of the seeds; and ensures the future prosperity of the plants. Hence it is, that a thinner soil, with a favourable subsoil, will produce better crops than a more fertile one incumbent on wet sand, or on cold and non-absorbent rock. Lands whose substratum consists of clean gravel or sand can bear little sun, owing to their not having the capacity of retaining moisture, and their generally possessing only a shallow surface of vegetable mould. In England this soil was formerly called rye-land, being more generally cropped with that species of grain than any other. When such soils are cultivated for barley, they should be sown early and thick, with seed soaked forty-eight hours in water or in the exudation from a dung-heap. Thus its simultaneous germination and its simultaneous ripening may be secured.

Sect. IV. Elevation of Lands relatively to Farming.

4764. The elevation of lands above the level of the sea has a material influence on the kind and quality of their produce. Land in the same parallel of latitude, other circumstance being nearly similar, is always more valuable in proportion to the comparative lowness of its situation.

4765. In the higher districts the herbage is succulent and nourishing, and the reproduction slower when the land is in grass; while the grain is less plump, runs more to straw, is less perfectly ripened, and the harvest is also later when the produce is corn. It has been calculated that in Great Britain sixty yards of elevation in the land are equal to a degree of latitude; or, in other words, that sixty yards perpendicularly higher, are, in respect of climate, equal to a degree more to the north. In considering the crops to be raised in any particular farm, attention ought therefore to be paid to its height above the level of the sea, as well as to its latitude. In latitude 54° and 55°, an elevation of 500 feet above that level is the greatest height at which wheat can be cultivated with any probable chance of profit; and even there the grain will prove very light, and will often be a month later in ripening than if sown at the foot of the hills.

4766. The usual maximum of elevation may be reckoned between 600 and 800 feet for the more common sorts of grain; and, in the backward secons the produce will be of small value, and sometimes will yield nothing but straw. It is proper, at the same time, to remark, that in the second class of mountains in the county of Wicklow, in Ireland, where no other grain is considered to be a safe crop, rye is cultivated with success. Where the soil is calcareous, however, as on the Gloucestershire and Yorkshire wolds, from the superior warmth of that species of soil, compared to cold clays or peat, barley grows in great perfection at an elevation of 600 feet above the level of the sea. Some experiments have been made to raise corn crops, at even a higher elevation, on the celebrated mountain Skiddaw, in Cumberland, but unsuccessfully.

4767. The greatest height at which corn will grow, in the more remote parts of Scotland, so as to yield any profit to the husbandman, is stated to be 360 feet above the level of the sea. At the same time corn has been produced, in other districts of that country, at still higher elevations, in particular at the following places: —

| Parish of Hume, in Roxburghshire | 630 | Doubruch, in Braemar, Aberdeenshire | 1324 |
| Upper Ward of Lanarkshire | 700 | Lead-hills, in Lanarkshire | 1564 |

4768. These and other instances of land being cultivated on high elevations, however, are merely small spots, richly manured, and, after all, producing nothing but crops of inferior barley and oats, and seldom fully ripe or successfully harvested. It is chiefly where the soil is sandy or gravelly, that corn will answer in Scotland on such elevated situations; and even then, only when the seasons are propitious, and where there are local advantages, favourable to warmth and shelter, in the situation of the lands.

Sect. V. Character of Surface in regard to farming Lands.

4769. A hilly irregular surface, whether at a high or low elevation above the sea, is unfavourable to farming. The labour of ploughing, carrying home produce, and carrying out manure, is greatly increased; while the soil on the summit of steep hills, mounts, or declivities, is unavoidably deteriorated. On the sides of slopes the finer parts of the clay and mould are washed away, while the sand and gravel remain. Hence the soil in such
PRACTICE and his to more the future, sun, heavy other important of various inferiority produce mediate.

Hence, while the soil to the north remains locked fast, and secured from waste, the other is loosened by the sun, and carried off by showers falling in the intervals of thaw.

Sect. VI. Aspect in regard to farming Lands.

Sect. VII. Situation of Farm Lands in regard to Markets.

The system of farming to be adopted on any particular farm, and the expense attending it, must materially depend on its situation in regard to markets; to the facility with which its produce can be conveyed, where a contiguous market is wanting; to vicinity to manure, to fuel, and to water.

Where markets are at hand, the farmer ought to take into consideration what articles will best suit those at a distance to which his produce must be sent. In such a situation, unless there are facilities for the conveyance of so bulky an article as corn by good roads, or by water-carriage, it is advisable, instead of cultivating grain, to attend either to the dairy husbandry, or to the breeding of stock which can be fattened in other districts where good markets are more numerous. This plan, by which the dairy, the breeding, and the fattening of stock, are made distinct professions, is highly beneficial to the farmer, and can be much cheaper in remote districts than where land is dear and labour high. On the other hand, the purchaser of lean stock avoids the expense and risk of breeding great numbers of animals. His attention is not distracted by a multiplicity of objects; he can alter his system from cattle to sheep, or from sheep to cattle, as is likely to be most profitable; his business is simplified, and the capital he lays out is speedily returned. The division of professions between breeding and feeding (though they may be united in circumstances peculiarly favourable), is on the whole a most important link in the progress of agricultural prosperity.

In regard to the facility of conveyance, the state of public roads, bridges, iron railway-ways, canals, rivers rendered navigable, and harbours, desires the consideration of the farmer, and will most materially influence the value of produce.

The situation of the farm in regard to manures, for an easy access to lime, chalk, marl, sea-weed, &c. is of essential advantage to cultivation. The price at which these articles can be purchased, their quality, their distance, and expense of conveyance, are likewise of importance. Farms, for example, possessing the advantage of sea-weed contiguous and in abundance, can pay from fifteen to twenty per cent. more rent per acre than others which could be otherwise benefitted.

In the cold and moist regions of Europe are important considerations to the farmer.

In the same county, even in England, the difference of expense is often material. In the Hebrides, from this aspect, the importance of the application of fuel is reckoned equal to a third part of the rent of the land; and farmers who pay, in some cases, 150l. per annum, would give 200l. if the landlord would supply them and their servants with fuel.

A farmer is under the necessity of using peat, from the labour attending the cutting, spreading, drying, and conveying it from a distance, several weeks of his horses and servants are devoted to that sole purpose; and much valuable time is lost, which ought to have been employed in the cultivation of his farm. It has been well remarked, that many farmers, to save five guineas on coal, often expend twenty, in thus misapplying the labour of their horses.

Where wood is used, it occupies a great deal of ground that might often be cultivated to advantage, and it is not of a lasting quality. Coal is preferable, for general purposes, to every other species of fuel, and besides its domestic application, its superiority for burning lime, that important source of fertility, or calcareous clay, also of much value to the farmer, is an object of great moment. The tenant, therefore, who resides in the neighbourhood of coal, more especially if limestone or calcareous substances are at no great distance, farms at less expense, can afford to pay a higher rent, and may derive more profit from the land he cultivates, than if in these respects he were differently circumstanced.
Sect. VIII. Extent of Land suitable for a Farm.

1871. The extent of ground which a farmer proposes to occupy demands due consideration. If it be beyond his capital to cultivate or improve, he can derive no profit by taking it. On the other hand, a small occupation may not be worthy of his attention.

1872. Farms as to size may be divided into three sorts: small farms under 100 acres; moderate-sized farms, from 100 to 200 acres; large farms, from 200 to 1000 acres, and upwards, of land fit for cultivation. The expense of labour is now so great, and the rent of land so high, that the profits of a small farm are not sufficient, with the utmost frugality, or even parsimony, to maintain a family with comfort.

1873. Moderate-sized farms are well calculated for the dairy system, for the neighbourhood of large towns, and where capital is not abundant. There are few trades in which a small capital can be employed to a greater advantage than in a dairy farm. There is no branch of agriculture where such a farm, with a constant and unremitting attention is required. That is not to be expected from hired servants; but it is an occupation of the wife and daughters of the farmer to perform, or at any rate to superintend, the whole business, and without which it cannot and it should not be attempted.

1874. Moderate-sized farms are general in the neighbourhood of towns. This necessarily results from the high rents paid in such situations; the shortness of the leases usually granted of land near towns; and the necessity the farmer is under of selling, in small quantities, the articles produced on his farm. On this subject it has been remarked, that farmers in the vicinity of large towns resemble retail shop-keepers, whose attention must be directed to small objects, by which a great deal of money is got, the greater part of which would be lost, without the most unremitting attention. The farmer at a distance from markets, who cultivates on a great scale, may be compared, on the other hand, to a wholesale trader, who, as his profits are less, requires a greater extent of land, for the purpose of deriving profit from an arable land, and of enabling him to support that station of life in which he is placed. There is this difference also between farmers in the neighbourhood of towns, and those who reside at a distance from them, that the former are profitably engaged, even when their profits, whether from their cattle, or their crops, are small; but, on the contrary, the inhabitants of the town, and of the suburbs, are not permitted to raise crops, or otherwise profit from their lands, as they can procure dung in return.

1875. For every one acre of the largest size the rent is subject to the capital required. A mountain breeding farm of 50.0 acres will not require more to stock it than an arable farm of 200 acres, and much less expense of labour on it. In all cases the safe side for the farmer to lean to, is to prefer a farm rather under than pressing his capital; and let him consider well beforehand whether he is going to commence a retail farmer, a manufacturer, or a merchant of any kind, or whether he can carry on an agricultural business without too much attention, and style of living of the one differs materially from that of the other. The subject of this section and the two following having been treated in a general way as between landlord and tenant in the preceding chapter, will be here only briefly noticed as on the part of the tenant.

Sect. IX. Tenure on which Lands are held for Farming.

1876. Perpetual tenures, or absolute property in land, can never come into consideration with a farmer looking out for a farm. A proprietor cultivating his own property cannot, in correct language, be said to be a farmer; for to constitute the latter an essential requisite is the payment of rent.

1877. The leases on which lands are let for farming are for various terms, and with very different covenants. The shortest lease is from year to year, which, unless in the case of grass lands in the highest order, and of the richest quality, or under some other very peculiar circumstances, no prudent man, whose object was to make the most of his skill and capital, would accept of. Even leases for seven or ten years are too short for general purposes, a greater extent of land, for the purpose of deriving profit from arable lands, so as to admit of the tenant paying a full rent; but fourteen years, when the lands to be entered on are in bad condition, are too few, and twenty-one years much better for the true interests of both parties. In farming, however, as in every other occupation where there are more skill and capital in want of employment than can find subjects to work on, farms will be taken under circumstances, both in regard to leases and rent, that are highly unfavourable to the farmer; and if they do not end in his ruin will keep him about six months laborious, and so little paid for his capital than any other way in which he could have employed it, but also infringe on its strength. The rent in the anticipation of current profit, took place in Britain during the wars against the French deceived many farmers, and flattered them for a time with the gradual rise of market prices after year. However high land might be taken at the commencement of a lease, it was always considered a consideration that it would be a bargain by the time it was half done; and that the farmer's fortune would be made during the last few years of its endurance. When the currency of Britain was permitted to find its level with that of other countries, the delusion ceased, and the majority of farmers were partially or wholly ruined.

1878. In regard to the covenants of a lease, it is necessary that there should be such in every one as shall protect both landlord and tenant. Certain general covenants in regard to repairs, renewals if necessary, timber, minerals, entry and exit crops, are common to all leases. Regulations as to manuring are required where hay and straw, turves, &c., are sold not to be consumed on the farm. Water meadows, rich old grass lands, copse woods, hop grounds, orchards, &c., require special covenants. Fewest covenants are required for a mountain breeding farm; and in all cases there should be a clause entitling the tenant to anyImprovements, arising from the landlord, and perhaps a jury of landlords or agents and farmers, against covenants as to cropping, repair, or renewals, which may, from extraordinary circumstances, press particularly heavy on the tenant.

1879. The power of the landlord to grant a lease, with liberal conditions, may in some cases be required to be ascertained by the tenant; and in Scotland, where it is illegal to sublet a farm unless a clause to that effect has been inserted in the original lease, a farmer may cease to be the master of his own property, unless he has taken care to see that clause inserted. In England, for the most part, subletting a farm is no more prohibited than renting a house or a shop. When the laws of country shall come to be founded on equity, this will be the case everywhere. At present they almost everywhere lean to the side of the powerful party, the landlord. In the progress of things it could not be otherwise.

Sect. X. Rent.

1880. The rent of land, in a general point of view, must always depend on a variety of circumstances; as the wealth of the country; its population; the price of produce; the amount of public and other burdens; the distance from markets; the means of conveyance; the competition among farmers; and other less important considerations; but the rent of any particular farm must be regulated by the nature of the soil; the duration
of the tenure, and the covenants contained in the lease; the capital to be invested by the farmer in its culture; and the expenses to which he is liable.

The rent of poor land cannot possibly be the same as in the case of fertile lands. The labour of ploughing, harrowing, sowing, &c., when the land is in cultivation, is nearly the same, and yet the produce is inferior, not only in quality, but in quantity. Indeed, where the produce is inconsiderable, or the cost of cultivation excessive, the whole, which is generally paid up by the expense of labour, and no rent whatever can be afforded, more especially in adverse seasons.

The duration of the tenure must have a considerable effect in fixing the rent. No farmer can afford to let land for a term of years if he believes he will lose money by it. The covenants, also, which are in fact a species of rent, must influence the money payments.

Rent must also depend on the capital invested in the cultivation of the farm. Thus, if a farmer can lay out only 4s. of capital per acre, he may not be able to afford for it a higher rent than 10s. per acre; but if he lays out 7s. he may pay 1ls. 5s. and with a capital of 10s. per acre, he may be enabled to pay 1s. or 2s. per acre.

The proportion of produce which should be paid as rent, is a question that has long been enquired into, by mystery and difficulty to resolve. Some have contended that one fifth was a reasonable proportion, while others contend for a fourth, or even a third part of the produce of arable land. But all farmer calculations on this subject are rendered fallacious by the effects of modern improvements. The rent ought certainly to depend upon the amount of the disposable produce; and that produce in grain is greatly augmented, both by a diminution of the consumption on the farm, effected by improved implements, and a more correct arrangement of labour, and likewise a better cultivation of the land in tillage. Hence, while the price of wheat has greatly advanced during the last twenty years, above the average price of the preceding twenty, the rent of land has not only risen, but in a higher proportion. More grain, and that of a better quality, has been produced on the same extent of land, and a greater amount of disposable surplus has gone to market. Out of this surplus disposable produce, it is evident that the rent must be paid. But it is difficult to divide it amongst the landlord and tenant. In some cases, it would work to the advantage of the former; and on the other hand, in the different articles which the farm produces. In bad seasons also, every deficiency of produce, in the acres set apart for supporting the tenant, must be made up from the disposable surplus; nor is it possible to apply the same rules to the estimation of various districts, or different crops, that are grown in the same district. It is proper, however, to give some idea of the proportion of produce paid as rent in Scotland and in England.

In Scotland, the following table states what is considered to be a fair proportion, where the land is cultivated. One of the most scientific agricultural writers, and, at the same time, one who has had much experience in farming, informs us that, "this table is a statement of Sir John Sinclair, who wishes to subject every thing to petty regulation; and that there is no such proportion recognised in Scotland:"

<table>
<thead>
<tr>
<th>Rent per acre.</th>
<th>Per acre.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Where land produces 10l. 10s. per acre annum, one third, or</td>
<td>£3 11 0</td>
</tr>
<tr>
<td>Where land produces 10l. 15s. per acre annum, one fourth, or</td>
<td>1 13 0</td>
</tr>
<tr>
<td>Where land produces only 10l. 5s. per acre annum, one fifth, or</td>
<td>0 17 0</td>
</tr>
</tbody>
</table>

It is considered that these proportions are not very different from the arable; namely, according to the quantity of stock they can maintain; and as they are not liable to the same expense of management, both the landlord and the tenant receive larger shares of the produce than in the case of arable farms.

In England, the tenant is allowed, on arable land, what is considered to be one moiety of the surplus, after defraying the expenses of cultivation, the taxes to which he is liable, and every other outgo. Hay land requires much less of his attention; and for this be only obtains one third of the surplus. But the profits of grazing depending much on superior judgment in buying and selling stock, as well as skill in preventing or curing their diseases, the grazer is entitled to a share of the surplus, fully equal to that of his landlord. It has been contended, as a general principle, that as both the expense of cultivating land, and the value of its produce, are infinitely various, a farmer ought to calculate what profit he can make on his whole farm, without entering into details; it being of little consequence to him whether he pays at the rate of 10l. or 15s. per acre, provided he makes an adequate interest on the capital invested. That is certainly a fair criterion on which a tenant may calculate what he ought to offer; but a landlord, in this case, he ought to bear in mind, will not accept of a price for the produce of land, which is not capable of yielding, and what proportion of it, or of its value, at a fair average, he has reason to expect, under all the circumstances of the case.

In England, compositions for tithe are computed as six is to twenty-two; so is the composition for tithe to the rent: so that land averaging 10l. 10s. per acre would, according to Sir John Sinclair's calculation, be charged for Rent | £2 11 7 |
Composition for tithe | 19 4 6 |

What the profits are to which a farmer is entitled, is a question much disputed. The proper answer is simply this: — The common profits of capital invested in other commercial undertakings. As the subject, however, will bear talking about, let us hear what is said in the Code on this subject. On the one hand, it is contended, that the produce of land is of such universal and absolute necessity to the existence of mankind, that it is not reasonable it should yield to him who raises it more than a fair profit. On the other hand it is urged, that a farmer is entitled to be fully compensated for the application of a considerable capital, exposed to the risk and uncertainty of the second economy, and conducted with industry and skill; and it has also been observed, that it is seldom some money is got by farming than an adequate interest for the capital invested. This is owing to competition, the articles produced being in numberless hands, who must bring them to market; and necessity, the goods of the farmer are so perishable, and the sale must be made when the price is sufficient to enable him to make, and the subsistence of his family. To prove how moderate the profits of farming in general are, it appears from the most careful enquiries, that on arable farms they rarely exceed from ten to fifteen per cent. of the whole rent, considered as sufficient, while a little more than an equal proportion may be expended on casualties than farming, or require more uniform attention. Some arable farmers, possessed of superior skill and energy, and who have got leave on reasonable terms, may exceed: from fifteen to twenty per cent.; while others, who are deficient in these qualities, or pay too high rents, frequently become insolvent; whereas the great majority of farmers are barely sufficient for the wants of their families; adding little or nothing to their capital, but that nominal addition which takes place in consequence of the depreciation of the currency.

PRACTICE of AGRICULTURE. Part III.

The case of grazing farming is different; as they are attended with less expense of labour, and produce articles of a more luxurious description, for which a higher price will be given. Hence, in such farms, fifteen per cent, and upwards is not unusual. Besides, the grazier is more of a trader than the mere arable farmer; he is frequently buying as well as selling stock; and sometimes makes money by judicious speculations, though occasionally, from a sudden fall of stock, his losses are considerable. The grazier who breeds superior stock, and thence incurs great expense, is certainly well entitled to more than common profit for his skill and attention.
TAXES, ETC., AFFECTING THE FARMER.

Sect. XI. Taxes and other Burdens which affect the Farmer.

4801. For the mode in which rent should be paid, and the terms of payment, we refer to the succeeding Book.

4802. Farmers are subjected to the payment of various taxes besides the rent paid to the landlord; some of them imposed for local purposes, and others for the general expenses of the state. The real amount of such burdens every careful tenant ought accurately to know before he bargains for his lease. They may be classed under the following heads: parochial, national, and miscellaneous.

4803. Parochial taxes are for the support of the clergyman, for the maintenance of the poor, and, in Scotland, for providing a parochial schoolmaster. The mode of supporting the clergy in England, by parochial rates, or the poor rate in kind, is highly injurious to the landed interest and generally injurious to the land itself, and, above all, injury to the improvement. It is a great bar to improvement, because an improving farmer, one more enlightened or more spirited than his neighbours, would pay more tithe by means of his outlay and his exertions, but it is not certain that he would likewise receive more profit. The produce would be more, but the expense would be greater. Nothing can be more dangerous than a law by which, when a person expends a large sum, either in reclaiming wastes, or augmenting the fertility of land already cultivated, he should be under the necessity of yielding up one tenth of its produce to a person who has been in no way liable to the expense, who has run none of the risk, and who has sustained none of the labour attending the improvement. A commutation of tithe, therefore, instead of its being exacted in kind, would be one of the greatest benefits that could be conferred on agriculture; and there is not the least difficulty in effecting it, by giving to the tithe-owner either a proportion of the land, or by converting the tithe into a perpetual corn rent. Both these plans have been adopted in a variety of cases, by local acts in England, and they ought now to be enforced as a general system.

4804. An assessment for the maintenance of the poor is another parochial burden, which is annually increasing, and which, if not specifically regulated by proper principles, will inevitably absorb a very large proportion of rent in England. Indeed, there are instances where, between the years 1813 and 1825, it has absorbed the whole. This tax is the most dangerous of all for the farmer, on account of its fluctuation (as from year to year it changes, but continually fluctuates); during cholera, in sickness, and in old age, assistance may be necessary; but, as Malthus justly observes, the poor-laws hold out support to the vicious and idle, at the expense of the prudent and the industrious. These payments also destroy the spirit of independence, and those ideas of honest pride which stimulate and direct the farmer in his labours. The latter, therefore, endeavours to prevent and to correct them; and, on its principle of payment, the burden is administered by the parish officers with caution and reluctance, and received by the poor with dissatisfaction and ingratitude.

4805. The tithes and the poor-rates are charges upon the land, and in fact come from the landlord's pocket rather than from the tenant's; but in their operation are often oppressive to the tenant, by rising in the course of the lease much higher than they were at the commencement; and as a farmer's rent is always considered in the course of the year to be his income, he is charged with it that while the tenantman, who receives the same annually, is charged with it to the poor on the amount of rent of his house.

4806. In Scotland, the poor are in general maintained by voluntary contributions; but when these are not found to be sufficient, the proprietors of the parish, with the clergyman and vestry, or Kirk-session, are directed to distribute the poor rates in the parish, and then to impose an assessment for their relief, one half to be paid by the proprietor, and the other half by the tenant.

4807. The national burdons in general, as the duties on houses and windows, and other assessed taxes, or assessments for the support of militia men's wives and families, for the convenience of vagrants, or the prosecution of felons, fall no heavier upon the farmer than upon other classes of the community.

4808. There are various miscellaneous burdens affecting the farmer, as statute assessments for bridges, which are of such public utility, that moderate rates for their maintenance, properly applied, cannot be objected to, statute labour on the highways; constable dues, which are seldom of much moment; charges of the churchwardens, including the repairs of the church; and in some populous parishes, there is sometimes a burial-ground tax. All these are paid by the occupiers. In some places, also, there is a sewer tax, chargeable on the landlords, where it is not otherwise settled by express contract.

4809. The occasion of such farm assessment in England is to subject, from year to year, uncertain burdens, operate as a premium to Scottish agriculture. It is ingeniously and justly remarked, that physical circumstances are much more favourable to agriculture in England than in her sister country; but these advantages are counterbalanced by a situation which might be removed, if the legislature would only settle on matters connected with the internal improvement of the country, and the means for promoting it, a portion of that attention which it so frequently gives to the amelioration or improvement of our foreign possessions. It ought to have been the business of the late Board of Agriculture to encourage the farmers to prevail on the legislature to relieve agriculture from its moral and political evils; but, instead of this, they set about procuring and distributing statistical and professional information, comparatively of very inferior utility; and after receiving from government nearly 50,000l. or, for any thing we know, more, lett agriculture what they found them. Even the line which the Board adopted, Marshall was a much more effectual instrument of agricultural improvement.

Sect. XII. Other Particulars requiring a Farmer's Attention, with a View to the Renting of Land.

4810. A variety of miscellaneous particulars require consideration before a prudent farmer will finally resolve to undertake the cultivation of a farm; as, the nature of the property on which the farm is situated; in particular, whether the estate is entailed, and to what extent the possessor of the estate is authorised to grant a lease; the character of the landlord, and, in case of his decease, that of his family, and of those whom they are likely to consult; the real condition of the farm in regard to the enclosures, drainage, buildings, &c.; the crops it has usually produced, and the manner in which it has been managed for some years preceding; the general state of the district, in regard to the price of labour, and the expense of living; the character of its inhabitants, in particular of the neighbouring farmers and labourers, and whether they are likely to promote or to discourage a spirit of improvement; the probability of subletting to advantage in case of not liking the situation, of finding a better bargain, or of death. The chances of settling one's family; as of marrying daughters, or of sons making good marriages. The social state of the farmers, or those that would be considered one's neighbours; the number and
tone of clergy, and lawyers; the game, and the chances of disputes concerning it; the morals of the serving class; schools, places of worship, &c. It is evident, that in hardly any one instance can all the circumstances above enumerated be favourably combined. But the active and intelligent farmer will not be discouraged by the obstacles he may have to surmount; but will strenuously endeavour, by exertion, industry, and perseverance, to overcome the difficulties he must unavoidably encounter. These are vague generalities, and may be thought too commonplace for a work of this description; but the young farmer on the look-out for a farm may not be the worse for having his memory refreshed by them.

Chap. II.

Considerations respecting Himself, which a Farmer ought to keep in view in selecting and hiring a Farm.

4811. Whoever intends to embrace farming as a profession, will be less likely to meet with disappointment, if he previously examines a little into his own disposition and talents; and weighs his expectations against ordinary results. Nor is it less essential that he should estimate justly the extent to which his capital may be adequate, and keep regular accounts.

Sect. I. Personal Character and Expectations of a professional Farmer.

4812. Every one who proposes to farm with success, Professor Thaer observes, ought to unite energy and activity, to reflection, to experience, and to all necessary knowledge. It is true, he says, farming has long been considered as an occupation fit for a young man incapable for any other, and such have sometimes succeeded; but this has always been chiefly owing to a fortunate concurrence of circumstances, which it is not now very easy to meet with.

4813. The practice of agriculture consists of an infinite number of particular operations, each of which appears easy in itself, but is often for that very reason the more difficult to execute to the precise extent required; one operation so often interferes with another. To regulate them according to the given time and strength, and in such a way that none is neglected, or causes the neglect of others, requires at once a great deal of attention and activity, without iniquity; of promptitude without precipitation; of general views, and yet with an extreme attention to details.

4814. To casualties and accidents no business is so much exposed as farming; and therefore, to enjoy an ordinary degree of happiness, Professor Thaer considers it essential that the farmer possesses a certain tranquility of mind. This, he says, may either be the result of a naturally philogemic habit of body, or of elevated views in religion or philosophy. These will enable him to bear with every misfortune arising from adverse seasons, or the death of live stock; and only permit him to regret accidents which result from his own neglect.

4815. The expectations of profit and happiness which a young farmer has formed ought to be well weighed against the profits and happiness of farmers in general. However superior a farmer may consider his own talents and abilities, he may rest assured there are a number as skilful and adroit as himself, and just as likely to realize extraordinary advantages. Let none therefore engage in farming, thinking to make more money than other farmers similarly circumstance with himself. If from a happy concurrence of circumstances he is more than usually successful, so much the better, and let him consider it as partly owing to good fortune, as well as good farming; but never let him set out on the supposition of gaining extraordinary advantages with only ordinary means.

4816. The profits of farming are much exaggerated by people in general; but it may be asserted as an unquestionable fact, that no capital affords less profit than that employed in farming except that sunk in landed property. This is the natural result both of the universality of the business and of its nature. Farming is everywhere practised, and every one thinks he may easily become a farmer; hence high rents, which necessarily lessen the profits on capital. From the nature of farming, the capital employed is turned seldom. A tradesman may lay out and return his capital several times a year; but a farmer cannot, generally speaking, grow more than one crop per annum. Suppose he succeeds in raising the best possible crops in his given circumstances, still his profits have an absolute limit: for if an ordinary crop be as five, and the best that can be grown be as seven, all that the most fortunate concurrence of circumstances will give is not great, and is easily foreseen. It is hardly possible for a farmer, paying the market price for his land, to make much more than a living for himself and family. Those few who have exceeded this, have found to have had leases at low rents; indigent landlords; to have profited by accidental rises in the market, or depreciation of currency; or to have become dealers in corn and cattle; and rarely indeed to have realised anything considerable by mere good culture of a farm at the market price.

4817. Many persons, chagrined with a city life, or tired of their profession, fancy they will find profit and happiness by retiring to the country and commencing farming. Independently of the pecuniary losses attending a change, new men are more certainly exposed to the generalities of men. The activity required, and the privations that must be endured, are too painful to be submitted to; whilst the dull uniformity of a farmer’s life to one accustomed to the bustle of cities, becomes intolerable to such as do not find resources in their fire-side, their own minds, or, as Professor Thaer observes, in the study of nature.

4818. The most likely persons to engage in farming with success are the sons of farmers, or such others as have been regularly brought up to the practice of every part of agriculture. They must also have an inclination for the profession, as well as a competent understanding of its theory or principles.

4819. In The Husbandry of Scotland, the case is mentioned of Walker, of Melkendean, an eminent
Sect. II. Capital required by the Farmer.

4820. The importance of capital in every branch of industry is universally acknowledged, and in none is it more requisite than in farming. When there is any deficiency in that important particular, the farmer cannot derive an adequate profit from his exertions, as he would necessarily be frequently obliged to dispose of his crops for less than their value, to procure ready money; and it would restrain him from making advantageous purchases, when even the most favourable opportunities occurred. An industrious, frugal, and intelligent farmer, who is punctual in his payments, and hence in good credit, will strive with many difficulties, and get on with less money than a man of a different character. But if he has not sufficient live stock to work his lands in the best manner, as well as to raise a sufficient quantity of manure; nor money to purchase the articles required for the farm; he must, under ordinary circumstances, live in a state of penury and hard labour; and the first unfavourable season, or other incident misfortune, will probably sink him under the weight of his accumulated burdens. Farmers are too generally disposed to engage in larger farms than they have capital to stock and cultivate. This is a great error; for it makes many a person poor upon a large farm, who might live in comfort and acquire property upon one of less extent. No tenant can be secure without a surplus at command, not only for defraying the common expenses of labour, but those which may happen from any unexpected circumstance. When a farmer farms within his capital, he is enabled to embrace every favourable opportunity of buying when prices are low, and of selling when they are high.

4821. The amount of capital required must depend upon a variety of circumstances; as whether it is necessary for the farmer to expend any sum in the creation, or in the repair, of his farm-house and offices; what sum an in-coming tenant has to pay to his predecessor, for the straw of the crop, the dung left upon the farm, and other articles of similar nature; the condition of the farm at the commencement of the lease, and whether any sums must be laid out in drainage, enclosure, irrigation, levelling ridges, &c.; whether it is necessary to purchase lime, or other extraneous manures, and to what extent; on the period of entry, and the time at which the rent becomes payable, as this is sometimes exacted before there is any return from the lands, out of the actual produce of which it ought to be paid; and, lastly, on its being a grazing or an arable farm, or a mixture of both.

4822. In pasture districts, the common mode of estimating the amount of capital necessary is according to the amount of the rent; and it is calculated that, in ordinary pastures, every farmer ought to have at his command from three to five times the rent he has agreed to pay. But in the more fertile grazing districts, carrying from 50l. to 100l. and even upwards, per acre (as is the case in many parts of England), five rents are evidently insufficient. When prices are high, ten rents will frequently be required by those who breed superior stock, and enter with spirit into that new field of speculation and enterprise.

4823. The capital required by an arable farmer varies, according to circumstances, from 5l. to 10l. or even 15l. per acre. An ignorant, timid, and puerile farmer lays out the least sum he can possibly contrive; and consequently he obtains the smallest produce or profit from his farm. The profit, however, will always increase, when accompanied by spirit and industry, in proportion to the capital employed, if judiciously expended. At the same time, attention and economy cannot be dispensed with. It is ill-judged to purchase a horse at forty guineas, if one worth thirty can execute the labour of the farm; or to lay out sums unnecessarily upon expensive harness, loaded with useless ornaments. Prudent farmers also, who have not a large capital at command, when they commence business, often purchase some horses still fit for labour, though past their prime, and some breeding mares, or colts; and in five or six years, they are fully supplied with good stock, and can sometimes sell their old horses without much loss. In every case, such shifts must be resorted to, where there is any deficiency of capital.

4824. A mixture of arable and grass farming is, on the whole, the most profitable method of farming. In the estimation of the advantage derived from the alternate policy, which are always considerable, the chance of profit are much more numerous from a varied system than where one object is exclusively followed. Where this mixed mode of farming is practised, the farmer will frequently rely on the; purchase of lean stock, instead of breeding his own; and derives great advantage from the quickness with which capital thus employed is returned. But, in that case, much must depend upon judicious selection. In general it may be said, that to stock a turnip-land arable farm, will require, at this time (1820), 5l. or 6l. and a chay-land farm from 7l. or 8l. per acre, according to circumstances.

This capital is necessarily divided into two parts. The one is partly expended on implements, or stock of a more or less perishable nature, and partly vested in the soil; for this the farmer is entitled to a certain annual gain, adequate to replace, within a given number of years, the sum thus laid out. The other is employed in defraying the charges of labour, &c., as they occur throughout the year, the whole of which, with the interest, should be replaced by the yearly produce. These two branches of expense on a farm are the first to be attended to, both in order of time, and in magnitude of amount.
PRACTICE

CHAP. III.

Choice of Stock for a Farm.

4826. The stocking of a farm may be considered as including live stock, implements, servants, and seed. A considerable portion of a farmer's capital is employed in manures, tillages, labour, &c.; but a farm being once engaged, the above are the only descriptions of stock which admit of a choice.

SECT. I. Choice of Live Stock.

4827. The animals required by a farmer are of two kinds; such as are employed to assist in labour; and such as are used to convert the produce of the farm into food, or other disposable commodities.

SUBSEC. I. Live Stock for the Purposes of Labour.

4828. The animals of labour used in British farming are exclusively the horse and the ox. Much difference of opinion formerly prevailed, as to which of these two animals should be preferred; and the preference has generally been given by speculative writers to the ox, and by practical farmers to the horse. Lord Kames in the last century, and Lord Somerville in the present, may be considered the principal advocates for the ox. To their arguments, and to all others, the following objections have been stated by the able author of the supplement to the 6th edition of The Gentleman Farmer; and they may be considered as conveying the sentiments, and according with the practice, of all the best informed and most extensive British farmers.

4829. The first objection is, that they are unfit for the various labours of modern husbandry,—for travelling on hard roads in particular,—for all distant carriages,—and generally for every kind of work which requires dispatch; and what sort of work often does not in this variable climate? A great part of a farmer's work is indeed carried on at home; and it may still be thought that this may be done by oxen, while one or more horse teams are employed in carrying the produce to market, and bringing home manure and fuel. But it is unnecessary to appeal to the author of The Wealth of Nations, to prove the impracticability of this division of labour, unless upon very large farms; and even on these the advantages of such an arrangement are at best extremely problematical. The different kinds of farm-work do not proceed at the same time; but every season, and even every change of weather, demands the farmer's attention to some particular employment, rather than to others. When his teams are capable of performing every sort of work, he brings them all to bear for a time upon the most important labours of every season; and when that is despatched, or interrupted by unfavourable weather, the less urgent branches are speedily executed by the same means. This is one cause, more important perhaps than any other, why oxen have ceased to be employed; for, whatever they can perform better than any other kind of work, is scarcely ever going forward all the year; and for some months in winter, the weather often prevents it altogether.

4830. Another objection is, that an ox team capable of performing the work of two horses, even such kind of work as they can perform, consumes the produce of considerably more land than the horses. If this be the case, it is of no great importance, either to the farmer or the community, whether the land be under oats, or under herbage and roots. The only circumstance to be attended to here is, the care of the ox; the value of this, in stating the consumption of produce, must be added to the value of his labour. He consumes, from his birth till he goes to the shambles, the produce of a certain number of acres of land; the return he makes for this is so much beef, and so many years' labour. The consumption of produce must therefore be divided between these two articles. And the share allotted to the animal, the contents of so many acres of grass and roots would produce the same weight of beef from an ox, bred and reared for beef alone, and slaughtered at three or four years old. Whatever has been consumed in producing labour. The next thing is to compare this consumption with that of the horse, which produces nothing but labour. By this simple test, the question, viewed upon a broad national ground, must evidently be determined. Every one may easily make such a calculation suited to the circumstances of his farm; none that could be offered would apply to every situation. But it will be found, that if even three oxen were able to do the work of two horses, the advantages in this point of view would still be on the side of the horses; and the first objection applies with undiminished force besides.

4831. The money-price of the horse and ox, it is evident, is merely a temporary and incidental circumstance, which depends upon the purchasing power of the farmer. A work ox may be got for less than half the price of a horse, because there is little or no demand for working oxen; while the demand for horses by manufacturers, commerce, pleasure, and war, enhances the price of farm-horses, as well as of the food they consume. Those who wish to see horses banished from all sorts of agricultural labour, would do well to consider where they are to be reared for the numerous wants of the other classes of society. Besides, if two oxen must be kept for doing the work of one horse, it ought to be foreseen, that though beef may be more abundant than at present, there will be a corresponding deficiency in the production of mutton and wool. A greater portion of the arable land of the country must be withdrawn from these mild purposes, and pastured directly, and kept under cattle crops, which, however necessary to a certain extent for preserving the fertility of the soil, do not return human food, on a comparison with corn crops, in so great a proportion as that of one to six from any given extent of land of the same quality.

4832. The demand for oxen is confined almost everywhere to the shambles; and by the improvements of modern husbandry, they are brought to a state of profitable maturity at an early age. No difference in price at setting to work,—no increase of weight while working,—no saving on the value of the food consumed, can ever make it the interest of tillage farmers generally to keep oxen as formerly, till they are eight or ten years old. They judiciously obtain the two products from different kinds of animals, each of them from the kind which is best fitted by nature to afford it, the labour from the horse, and the beef alone from the ox. And though the price of the horse is almost wholly sunk at last, during the period of his labour he has been paying a part of it every year to a fund, which, before his usual term expires, becomes sufficiently large to indemnify his owner. The ox, on the other hand, is changed three or four times during the same
CHOICE OF LIVE STOCK.

783

period; and each of them gives nearly as large a careen as the food of man as if his days had been impossibly prolonged in executing labour, from which he has been gradually exempted in Britain, in France, and in other countries, very nearly in proportion to the progress of correct systems of husbandry.

4833. The description of horse which a farmer ought to choose will depend chiefly on the soil of the farm, and partly also on the quantity of road-work. Stiff lands require obviously a heavier and more powerful breed than such as are light and hilly. In the latter case, two of the best breeds are the Cleveland and Clydesdale, or some local cross with these breeds. In general, it is not advisable to procure horses from a climate materially different from that where they are to remain; and therefore, for various reasons, a prudent farmer will look out for the best in his neighbourhood. Often, however, he is obliged to take the stock of his predecessor; and this he can only get rid of or improve to his mind by degrees. The farm-horses in most parts of England are much too cumbersome and heavy, and are more fitted for drawing heavy drays or waggons in towns than for the quick step required in the operations of agriculture.

4834. The objections of Davis of Longleat to the using of large heavy-heeled horses, in preference to the smart, the active, and the really useful breeds, merit particular attention. In some situations, the steepness of the hills and the heaviness of the soil require more than ordinary strength; but, in such cases, it maintains that it would be better to add to the number of horses than to increase their size. Great horses not only cost proportionally more at first than small ones, but require much more food, and of a better quality, to keep up their flesh. The Wiltshire carter also takes a pride in keeping them as fat as possible; and their food (with a greater or less allowance, according as the situation of the farm may place them in a more or less easy or difficult manner of keeping) is generally much more expensive. In keeping a fine team of horses amounts nearly to the rent of the farm on which they are worked. They are purchased young when two years' old colts, and sold at five or six years of age for the London drays and waggon work. The price of these horses is very seldom counterbalanced by the difference of price, more especially as such horses are generally worked when young, that they may attain their full size and beauty. In sloughing light soils, the strength of a dray-horse is not wanted; and in heavy soils, the weight of the animal does injure to the land.

SUBSEC. 2. Choice of Live Stock for the Purposes of breeding or feeding.

4835. The most desirable properties of live stock destined for food are considered in The Code of Agriculture, in size, form, a tendency to grow, early maturity, hardi-ness, constitution, prolific properties, quality of flesh, a disposition to fatten, and lightness of offal.

4836. The bulk of an animal was the sole criterion of its value before the improvements introduced by Bakewell. A cow could give the greatest quantity of milk, and much regard was paid to the price the animal ultimately fetched than to the cost of its food. Of late, since breeders began to calculate with more precision, small or moderate-sized animals have been generally preferred, for the following reasons:

4837. Small-sized animals are more easily kept, they thrive on shorter herbage, they collect food where a large one cannot reach it. They suffer less from extreme cold, their meat is more profitable, and their richer gravy, has often a superior flavour, and is commonly more nicely marbled, or veined with fat, especially when they have been fed for two years. Large animals are not so well calculated for general consumption as the moderate-sized, particularly in hot weather; large animals peach pastures more than small ones; they are not so active, require more rest, collect their food with more labour, and will only consume the nicer and more delicate sorts of plants. Small cows of the true dairy breeds give proportionally more milk than large ones. Small cattle may be fattened solely on grass of even moderate quality, and require more pasture, or at least a pasturage much more extensive. This is more in keeping the profit of the farmer. It is much easier to procure well-shaped and kindly-feeding stock of a small size than of a large one. Small-sized cattle may be kept by many persons who cannot afford either to part with the larger or yet to maintain so large a family, if in any accident should happen to them, can be more easily borne. The small-sized sell better; for a butcher, from a conviction that, in proportion to their respective dimensions, there is a greater superabundance of valuable parts in a small than a large animal, will give more money for two oxen of twelve stone each per quarter than for one of twenty-four stone.

4838. In favour of the large-sized it is, on the other hand, contended, that without deeming whether from their birth till they are slaughtered the large or the small one eats most for its size, yet on the whole the large one will pay the grayer or the farmer who fattens him as well for his food; that though some large oxen are coarse-grained, yet where attention is paid to the breed (as is the case with the Herefordshire), the large ox is as delicate food as the small one; that if the small-sized are better calculated for the consumption of private families, of villages, or of small towns, yet that large cattle are fitter for the markets of great towns, and in particular of the metropolis; that were the flesh of the small-sized ox better when fresh, yet the meat of the large-sized is unquestionably more calculated for salting, a most essential object in a maritime and commercial country, — for the thicker the better, the better it will retain its juices when salted, and the fitter it is for long voyages; that the hide of the large ox is of very great consequence in various ways, if large-sized cattle are kept for a general & distinguished purpose of disposition; that where the pastures are good, cattle and sheep will increase in size, without any particular attention on the part of the breeder; large animals are therefore naturally the proper stock for such pastures; that the art of fattening cattle, and even sheep, with oil cake, being much improved and extended, the advantage will be of large oxen; unless large oxen were frequently fed, the different provision of grass and turnips with oil-cake; and, lastly, that large oxen are better calculated for working than small ones, two large oxen being equal to four small ones in the plough or the cart.

4839. Of these arguments generally made use of on both sides of the question; from which it appears that much must depend upon pasturage, and kind of consumption. It is obvious that both sides have their advantages. The intelligent breeder, however, (unless his pastures are of a nature peculiarly forcing,) will naturally prefer a moderate size in the stock he rears. Davis of Longleat, one of the ablest agricultural writers, has produced some useful observations on his own situation, which are all, he says, circumstances in the plantations that the attempts which have been made to improve the breeds of cows, horses, and sheep, have proceeded too much upon the principle of enlarging the size of the animal; whereas, in general, the only real improvement has been in reducing its size, and introducing a kind that will live harder, and come to greater perfection at an earlier age.

4840. Though it is extremely desirable to bring the shape of cattle to as much perfection as possible, yet profit and utility ought not to be sacrificed for mere beauty which may please the eye, but will not fill the pocket; and which, depending much upon caprice, must be often changing. In regard to form, the most experienced breeders seem to concur in the following particulars. — That the form or shape should be compact, so that no part of the animal should be disproportioned to the other parts, and the whole should
be distinguished by a general fullness and rotundity of shape; that the chest should be broad, for no animal whose chest is narrow can easily be made fat; that the carcase should be deep and straight; that the ribs should be well rounded; that the fat is more distributed than when it is concave; that the head shows a diseased state, and in older ones it is considered a proof that the animal will not return in flesh, in milk, or in labour, the value of the extra quantity of food which it consumes; that the legs should be strong, while the ribs are not concave, and that the bones of the head and other parts of inferior value, should be as small as is consistent with strength, and with the other properties which the animal ought to possess.

In animals bred for the shambles, the form must likewise be such as to contain the greatest possible proportion of flesh and the least value of the softer and more delicate parts which are apt to be lost in the process of dressing, and thus the wishes of the consumer may be gratified. As to the broad legs, and full hips, which are considered as a point of excellence in particular breeds, it is evident that the old narrow and long-legged, which are required in improvement, but the alteration is now carried to a faulty excess, and often occasions great difficulty and danger in caressing.

481. The form of animals has fortunately attracted the attention of an eminent surgeon, Henry Cline, Esq. of London, whose doctrines we have already had laid at length, and the substance of which is:—The form of any animal, whether it be the internal or external, is only the result of the action of the principle which is most instinctively attended to, for on their size and soundness the health and strength of an animal principally depend; that the external indications of the size of the lungs are the form and size of the chest; that particularly the head should be small as by this it affords other advantages in feeding, &c., and as it generally indicates that the animal is of a good breed; that the length of the neck should be in proportion to the size of the animal, that it may collect its food with ease; and that the muscles and tendons should be large, by which an animal is enabled to travel with greater facility. It was formerly the practice to estimate the value of animals by the size of their bones. A large bone was considered to be a great merit; and a fine-boned animal always implied great size. It is now known that this doctrine was carried too far. The strength of the animal does not depend upon the bones, but on the muscles; and when the bones are disproportionately large, it indicates, in Cline's opinion, an imperfection in the organs of nutrition. Bakewell strongly insisted on the advantage of small bones; and the celebrated John Hunter declared, that small bones were generally attended with corpulence in all the subjects he had an opportunity of examining. A small bone, however, being heavier and more durable, requires a larger quantity of food to nourish than a heavy bone, and hence the bones get the same size, at the same time, a gauntness and paucity of intestines should be guarded against, as a most material defect, indicating a very unthriving animal. Being too light of bone, as it is termed, is also a great fault. A good stock-bred, has always a fine-boned, but an unthriving-sized bone, and growers is inseparable, but one whose progeny takes an unnatural or gigantic size ought to be avoided.

482. Among the qualities for which thorough-bred cattle and sheep are distinguished, that of being good growers, and having a good length of frame, is not the least essential. The meaning of which is, that the animal is obtained on a stock of a constitution peculiarly healthy and productive of thin flesh. As specimens of rapid growth, a steer of three years old, when well fed, will weigh from 80 to 100 stone, 14lb. to the stone; and a two-year old Leicesters wether, from 75 to 285 lb. per quarter, immediately after his second daie he is taken from him. Animals having the property of growing, are usually straight in the neck, and their shoulders are well armed with sinews; at the same time, a gauntness and paucity of intestines should be guarded against, as a most material defect, indicating a very unthriving animal. Being too light of bone, as it is termed, is also a great fault. A good stock-bred, has always a fine-boned, but an unthriving-sized bone, and growers is inseparable, but one whose progeny takes an unnatural or gigantic size ought to be avoided.

483. Arriving soon at perfection, not only in point of growth or size, but in respect of fatness, is a material object for the farmer, as his profit must in a great measure depend upon it. Where a stock-bred are kept, the price not only of the hides, but of the flesh, is raised, and profit to the feeder, but in general, too, a greater value for their consumption, than slow-feeding animals. This desirable property greatly depends on a mild and docile disposition; and as this docility of temper is compatible with the manner in which the animal is brought up, attention to it will be found to be well bestowed. It is under these circumstances that such animals are produced. The property of early maturity, that a very numerous consumption of meat is great, is extremely beneficial to the public, as it evidently tends to turn greater supplies to the market; and this propensity to fatten at an early age is a sure proof that an animal will fatten speedily at a later period of his life.

484. The formation of a hardy constitution, is, in the wilder and bleaker parts of a country, a most valuable property in stock. Where the surface is barren, and the climate rigorous, it is essential that the stock bred and maintained there should be able to endure the severities and vicissitudes of the weather, as well as scarcity of food, hard work, or any other outward exposure to their own danger. In this respect, different kinds of stock greatly vary; and it is a matter of much consequence to select, for different situations, cattle with constitutions suitable to the place where they are to be kept. It is a popular belief, that dark colours are indications of hardiness. In mountainous places, a rough and hardy kind of cattle, when properly to be kept out all winter: it enables them to face the storm, instead of shrinking from it. Hardy breeds are exempted from various diseases, such as having yellow fat, and being blackdfleshed, defects so injurious to stock.

485. The prolific quality of a breed is a matter deserving attention. The females of some breeds both bear more frequently than usual, and also have more frequently than one at a birth. This property runs more strikingly in sub-varieties, or individual families; and though partly owing to something in the habits of animals, and partly to their previous good or bad treatment, yet in some degree seems to depend upon the seasons, some years being more distinguished for twins than others. In breeding, not only the number, but the sex of the offspring, in some cases, seems to depend upon the female parent. Two cows producing fathe offspring, though the four offspring are produced every year, it is observed that when they produced a bull calf, it was in the same year. Under similar circumstances, a great number of males have been produced by the same cow in succession, but not to the same extent.

486. By the quality of their flesh, breeds are likewise distinguished. In some kinds it is more delicate, hard, and aromatic. In some parts of the UK, the texture of the meat is superior; the gravy they produce, instead of being white and insipid, is high coloured, well flavoured, and rich; and the fat is intermixed among the fibres of the muscles, giving the meat a streaked, or marbled appearance. The fat of these breeds is the most valuable. Hence two animals of nearly the same degree of fatness and weight, and who could be fed at nearly the same expense to the human, will sell at very different prices, merely from the known character of their meat.

487. A disposition to fatten is a great object in animals destined for the shambles. Some animals possess that of a finer nature than others of their live, and then it only takes place at a more advanced period, when they have attained their full growth, and are furnished at the same time with a sufficient supply of food. There are in this respect other distinctions: most sorts of cattle and sheep, which have not especially contrived for lowland pastures, are fat, while the fat continues, whereas in the case of a breed, which would barely live; some animals take on fat very quickly, when the proper food has been supplied, and some individuals have been found, even in the same breed, which have, in a given time, consumed the least proportional weight of the same food, but have not, till the proper food, go yet being of the same size or weight. It is probably from internal confirmation that this property of rapid fattening is derived.

488. The advantages and disadvantages of fattening cattle and sheep, at least to the extent frequently practised at present, are points that have of late attracted much public attention. But any controversy
on that subject can only arise from want of proper discrimination. Fat meat is unquestionably more

nourishing than lean, though to digest this oily matter there are, on account of its difficult

solubility, a good bile, much saliva, and a strong stomach; commonly none, except those who are in

the good health, has state of health, can properly digest it. There is no fat meat, however, is unfit for general consumption, yet experiments in the art of fattening animals are likely to produce useful discoveries; and though, in the course of trying a number of experiments, errors and

embarrassments, it should be observed, yet an advantage may be derived from those unsuccess

As the bone also gains but little in the fattening animal, and the other offal becomes propor

tionably less, as the animal becomes more fat, the public has not sustained much loss by over-fatted ani

mals. To kill even hogs till they are thoroughly fat, is exceeding bad economy. An ox or cow, though

the little flesh it has may be of good quality, yet presents, when lean, little but skin and bone; and if

slaughtered in that state, would neither indemnify the owner for the expense of breeding and maintaining

it, nor benefit the public. A course and heavy-fleshed ox, which would require a very long time and

much good forage, and be slaughtered with most advantage while it is rather lean, than to attempt to

so much the extent of fat, as the want of a sufficient quantity of lean flesh, of which the consumer com

plains; for it cannot be doubted, that the lean flesh of a fat animal is better in quality, and contains

more waking spirit, than the flesh of an ox, or cow. (Code, &c.)

4349. Handling well. The graziers and butchers in various parts of the kingdom have recourse to

feeling the skin, or cellular membrane, for ascertaining a disposition to fatten; and since Bakewell

directed the public attention so much to breeding, that practice has become more generally known.

Handling cannot easily be defined, and can only be learned by experience. The skin and flesh of cattle, when handled, should feel soft to the touch, somewhat resembling that of a mole, but with a little more

resistance to the finger. A soft and mellow skin must be more pliable, and more easily stretched out, to

receive any extraordinary quantity of fat and muscle, than a thick or tough one. The rigid-skinned

animal must, therefore, always be the most difficult to fatten. In a good sheep, the skin is not only soft

and mellow, but in some degree elastic. Neither cattle nor sheep can be reckoned good, whatever their

shapes may be, unless they are first-rate handlers. The improved short-horned breed, besides their mel

lowness of skin, and great distinguishing by softness and slickness of hair.

4350. Lighthness of offal. An animal solely bred for the shambles should have as little offal, or parts of

inferior value, as possible (consistently with the health of the animal), and consequently a greater propor

tion of meat may be applicable as food for men. This, therefore, the skilful farmer will also keep in view in

selecting his species of stock. (Code, &c.)

4351. The Rev. Henry Berry, who has paid much attention to the subject of breeding and

feeding cattle, and written several valuable papers on the subject in the British

Farmer's Magazine, seems to prefer for general purposes the improved short-horns.

"These cattle," he says, "at three years old, are equal to Hereford cattle at four years

old; and they are bred from cows which prove much more profitable for the dairy than the

Herefords." At the same time, he admits that the Hereford cattle are excellent to

purchase with a view to fattening, because in a lean state at four years old they will of

course not bear an increased price in proportion to the increased time required to

render one of them equal to a short-horn of three years. For breeders, therefore, he

decides decidedly the short-horns; and he has given an interesting history of

this breed of cattle for the last eighty years, the period which has elapsed since

it attracted attention. It was imported from Holland to the banks of the Tees; and,
or, at least, it is the result of a cross between the breed so imported and the native

breed of that district. (Improved Short-Horns, &c. By the Rev. Henry Berry. 2d edit.

1830.)

SECT. II. Choice of Agricultural Implements, Seeds, and Plants.

4352. The variety and excellence of agricultural implements is so great, that the prudent

farmer, in regard to these as well as in every other branch of his art, must study economy. He

should not incur an unnecessary expense in buying them, or in purchasing more

than an essentially requisite, and can be profitably used. This maxim ought to be more

especially attended to by young improvers, who are often tempted, under the specious

ideas of diminishing labour and saving expense, to buy a superfluous quantity of imple

ments, which they afterwards find are of little use. (Coventry's Disc. p. 47.) It is

remarked by an intelligent author on matters of husbandry, that a great diversity of

implements, as they are more rarely used, prove in general a source of vexation and dis

appointment, rather than of satisfaction, to the farmer.

4353. The different implements required by the farmer are: those of tillage; for drilling or sowing

corn, for harrowing corn; for harvesting corn; for threshing and cleaning corn; for mowing and harvest

ing hay; of conveyance; for draining; for harnessing stock; for rolling land; for the dairy; and, for

miscellaneous purposes.

4354. Purchasing implements, the following rules are to be observed: they should be simple in their

construction, both that their uses may be more easily understood, and that any common workman may be

able to repair them when they get out of order; the materials should be of a durable nature, that the

labour may be less liable to interruption from their accidental failure; their form should be firm and

compact, that they may not be easily moved, shaken, or jolted; and that they may be more safely worked

by country labourers, who are but little accustomed to the use of delicate tools. In the larger machines,

symmetry and lightness of shape ought to be particularly attended to: for a heavy carriage, like a good

horse, should be as light as possible; the work should be cut up and placed in a position the best calculated to resist pressure; and mortises, so likely to weaken the wood, as much as possible, be avoided; at the same time, implements should be made as light as

is excusable, because with that labour, they are much more likely to cause the most serious c

less repairable damage. Their price should not be considered a drawback; but it is to be remembered that labourers, the labourers, are not so cheap as they were long ago, and that circumstances can afford to buy them; yet for the sake of a low price, the judicious farmer will not pur

chase articles either of a dimly fabric or a faulty form; and implements ought to be suited to the nature

of the country, whether hilly or level, and more especially to the quality of the soil; for those which are

calculated for light land will not answer equally well in soils that are heavy and adhesive. (Code.)

4355. In the choice of seed corn, regard must be had to procure it from a suitable soil and climate, and of a suitable variety. A change from one soil to another of a different

3 E
quality, is generally found advantageous; but this is not always the case as to climate. Thus, some of the varieties of oats, as the Angus oat, which answers well in most parts of Scotland, is found not to fill in the ear, but to shrivel up after blossoming, in the south of England. In like manner, the woolly-chaffed white wheats of Essex and Kent rot in the ear when grown in the moist climate of Lancashire. In settling on a farm in a country with which the farmer is little acquainted, he will often find it advisable to select the best seed he can find in the neighbourhood, and probably to resist it and free it from the seeds of weeds and imperfect grains. Particular care is requisite in selecting the seed of the bean and pea, as no crop depends more on the variety being suited to the soil and climate. Thus, on hot gravelly soils in the south, the late grey pea would produce little haulm and no pulse; but the early varieties, or the pearl pea, will produce a fair proportion of both.

4556. The only small seeds the farmer has to sow on a large scale, are the clovers, grasses, the different varieties of turnip, and probably the mangold wurzel and carrot. No expense or trouble should be spared to procure the best turnip seed; as if that is either mixed by impregnation with other varieties of the Brassica tribe, or has been raised from a degenerate small-rooted parentage, the progeny will never come to any size. The same may be said of carrot or mangold seed, raised from small misshapen roots. Even rape seed should be raised from the strongest and largest rooted plants, as these always produce a stronger progeny.

4557. The selection and propagation of improved agricultural seeds has till lately been very little attended to. But the subject has been taken up by Mr. Sinclair of New Cross, Mr. Shirreff of Mungos Wells, Mr. Gorrie of Raith, and others; and we have little doubt some greatly improved varieties of our most useful field plants will be the result. Mr. Shirreff mentions (Quart. Journ. Ag. vol. i. p. 356,) that the variety of turnips called Dutch is that which was propagated by the Duke of Argyll at Dalmally, and which seed was saved, in improved in nutritious value upwards of 300 per cent. "Potatoes and Swedish turnips," Mr. Shirreff says, "appear to be susceptible of further improvement by judicious selection. Two different varieties are used in this country, with varying degrees of success, but which have become spurious. But whatever may be the degree of improvement of which the agricultural produce of the country is susceptible, by the propagation of genuine seeds of the best varieties of plants, one remarkable feature of such an improvement is, that it could be carried into effect without any additional investment of capital, or in other words, that already-embraced varieties would be improved, not merely by slight care and observation, but by a single exercise of patience in their propagation. The whole increase of produce obtained by such means would not only support the unproductive part of the population, but the greatest part of a man's farm, to the occupier, and ultimately to the owners of land. The difference of produce, arising from sowing the seed of a good and a bad variety of a plant, is so great, that it does not seem inconsistent with probability to state, that the gross agricultural produce of the country might be augmented, in the course of a few years, through the agency of improved seeds, to the amount of seven per cent.; and as the farmer's home consumption of produce, by such means, would be increased nearly ten per cent., what an enormous fund this forms for maintaining the unagricultural part of the population, and augmenting the income of landholders.

4558. The facility of propagating genuine seeds, will become manifest from a statement of my practice. In the spring of 1828, a vigorous wheat-plant, near the centre of a field, was marked out, which produced 63 ears, that yielded 2473 grains. These were sown in the autumn of the same year; the produce of the seed afterwards sown was the least in the world, and the harvest of the first season of nearly forty quarters of sound grain. In the spring of this year, I planted a fine purple-top Swedish turnip, that yielded (exclusively of the seeds picked by birds, and those lost in threshing and cleaning the produce,) 109,296 grains, a number capable of furnishing plants for upwards of 50,000 acres. The produce of the same variety the following July, with the same crop, of which it is in contemplation to sow for the same purpose in July 1829, in short, if the produce of the turnip in question had been carefully cultivated to the utmost extent, the third year's produce of seed would have supplied the greatest British island of Great Britain with seed.

4559. Plants and animals are both organic bodies, from the germs of whose fecundating organs proceed new races, which yield crops; and thus an extensive view of improving agriculture through the agency of genuine seeds embraces the propagation of live stock. Now, however important the propagation of live stock may be, when considered by itself, yet, when viewed in connection with our agricultural system, embracing the cultivation and improvement of the herbage which support animals, as well as those plants, parts of which form the ingredients of human sustenance, it becomes less imposing. The analogy subsisting between animal and vegetable life is known and acknowledged; and it may be stated, that the union of the male and female organs of different varieties of a plant, under favourable circumstances, produces a new race, which partakes of the qualities of both parents, and which is termed a hybrid. Now, hybrid varieties of agricultural plants, when suffered to intermingle with the original grain, will produce like cross-bred varieties in their intercourse with the general herd, till the character of the stock becomes changed, and consequently deteriorated or improved. In either case, propagation from the best variety alone would be attended with good effects. The propagating vegetable life and animals in the same way, the vegetables must exceed that of animals in importance, as much as the vegetable produce of the country surpasses that of animals. Indeed animals may justly be considered mere machines for converting our inferior herbage into nutriment of a different description; grasses and roots are the raw materials, butcher's meat the manufactured commodity.

4560. The importance of attending to varieties of cultivated plants has been ably pointed out by Mr. Bishop, at once a scientific botanist and an experienced practical gardener. By means of various varieties of the same species, the gardener can have gardens and a table of vegetables, which the quality of the produce is improved in a still greater proportion. In them we perceive the labour and assiduity of man triumphing over the sterility of unassisted nature, and succeeding in giving birth to a race of beings calculated to supply his wants in a manner that original species never could have done. The differences between varieties that have sprung from the same species suits them for different purposes, and for different soils, situations, and climates. Some, by reason of their robust natures, are winter vegetables; others, by being early, are spring vegetables; while some are tender in summer, and others in autumn, whilst others in winter. Thus, the beet can eat when pulled off the tree, while the fruit of others is valuable by reason of its keeping till that season, when Nature rests to recruit her strength. Thus, in edible plants and fruits, we are supplied with an agreeable change throughout the year, from a diversity of varieties that spring from the same species. In the earlier ages of the world, no idea could have been entertained of the
excellence some varieties have attained over their originals. Who, upon viewing the wild cattage that grew about the camp, would have believed that such grain could have been produced by the same? Or who would expect the well-formed apple of a pound's weight from the vegetation of our hedges? Many instances might be noticed of original species that are scarcely fit to be eaten by the best hands of the field, the varieties of which afford a nutritious and wholesome food for man. Upon comparing the original plants with those of the Parnassus of the seedling, in which the climate, with their greater superiority, and, in comparison with the climate, with their greater interiority, and cannot help reflecting on the helpless condition of that hungry savage who first taught us the use; for nothing short of the improvement attending to that discovery, which has long been the object of obvious, upon comparing original species with their varieties produced by culture, than that we, by means of the latter, enjoy a vegetable food far preferable to that of our forefathers; a circumstance from which it may be inferred that prosperity is destined to enjoy a better than that which we do now. For although it is reasonable to believe that there is a degree of excellence of species derived from the superior culture to which they have been subjected, yet as that degree is unknown, and as it is probably beyond the power of man, of cultivation, or of time, to determine the same, we are justified in regarding it as progressive, and in considering the new native food good enough of itself, without any sign or barbinger of improvement. 

4831. The power of distinguishing varieties, and of forming some idea of their worth at sight, is an art which valuable varieties may sometimes appear to those who have not time to prove their real trial; and if they have, the probability is, that the means to be employed require more care, time, and cost than the plants are worth to the person to whom they are doubtfull: whereas, were such persons capable of forming an estimate of the worth of varieties from their appearance, then would they use systems for their preservation, whenever their appearance was found to deserve superiority. That this is an attainment of considerable importance, is beyond all question allowed; yet, that it, in some cases, requires the most strict attention, appears from the circumstance of varieties being oftentimes valuable, though not conspicuously so. Let us suppose, for instance, that in a field of wheat there exists a plant, a new variety, having two more fertile joints in its spike, and equal to the surrounding wheat in every other respect, a main accustomed to form such a variety would scarcely observe such a variety, unless otherwise distinguished by some peculiar badge; nor would any but a person versed in plants know that it was of superior value if placed before him. How many varieties existing, the mixture, and extent of their observation are, therefore, have been carefully noticed, and of which they have been proved to be valuable in the community! The number of fertile joints in the spike of the wheat generally cultivated, varies from eighteen to twenty-two; the number, however, in the inhabitants of Grains, of Scotland, and Ireland amount to nearly the same number of millions: therefore, as the wheat produced in those islands has been of late years sufficiently supplied the inhabitants thereof with bread, it is evident that a variety with two additional fertile joints, and equal in other respects to the varieties at present in cultivation, would, when it become an object of general circulation, be of great value, for, with two millions of people, a double staffer, or at least twenty acre being brought into cultivation, or one additional drop of sweat from the brow of the husbandman.

4852. The same varieties are not repeatedly produced by culture; if they were, there would not exist that necessity for strict observance on the part of observers; because, if a variety were lost or destroyed, we might look forward to its reappearance: or did we produce it, care was required in cultivating, and of producing them late or early, tall or dwarf, sweet or sour, or just as we might wish to have them, then might we plead an excuse for inattention. But experience shows, that when a variety is lost, it is for ever lost; and, if most delicate reflection cannot fail of convincing us, that our power of producing them is most limited. Indeed, our knowledge only enables us to produce those of the intermediate kind; while varieties that confer extension or excellence are as likely to be produced from the seed sown and treated by the same probable labourers as from those sown and treated by the ablest husbandman, the most skilful botanist, or most profound philosopher of the age. From this it is obvious that the same benefits mankind derive from the varieties produced by culture are numerous and important, and that the discovery of those of merit is an object highly deserving of our attention." (Bishop’s Casual Botany)

4863. The varieties of wheat and barley in general cultivation, Mr. Gorrie observes, are "not numerous; but were a part of that attention paid to the production of new and improved varieties of field-beans, peas, oats, barley, and wheat, which is now almost extended to live stock, the same success might follow; and varieties of each of these useful species of grain might be found as far surpassing those now in cultivation as the modern breeds of horses and cattle surpass those of former days. To effect this, a simple process only is necessary. When any two varieties are intended to be used in crossing, it is requisite that the pollen of one of the periods as may not fail of convincing us, that our power of producing them is most limited. Indeed, our knowledge only enables us to produce those of the intermediate kind; while varieties that confer extension or excellence are as likely to be produced from the seed sown and treated by the same probable labourers as from those sown and treated by the ablest husbandman, the most skilful botanist, or most profound philosopher of the age. From this it is obvious that the same benefits mankind derive from the varieties produced by culture are numerous and important, and that the discovery of those of merit is an object highly deserving of our attention." (Bishop’s Casual Botany)

4864. Grain, seeds, and roots intended for reproduction are not required to have come to the same degree of maturity on the plant, as when intended for meal or other products to be consumed as food. The latter are always explained; all the parts of the grain being esteemed with a greater care as the cotyledons of the seed are better fitted for entering the vessels of the minute plant, when they are not of that same farinaceous nature, as when those cotyledons are more mature. That grain not perfectly matured is fully qualified for seed, is evident from places situated near rivers or lakes, where the grain is more accessible to the climate; but private situations can be prolonged till the bran is mellowed. This happens in autumn, before the grain is matured, and is probably caused by fogs or damp which arise from the water. This blast discovers the straw, and renders it so friable that it will hardly bind itself; the ear is in this state drawn and little seed is seen, neither is there danger of the sheath being split, and so small a quantity of farinaceous matter will be contained in the grains, that a sheaf, after being reaped, will feel as light in the hand as if it had been previously threshed; and yet, for as bad as it appears, it is commonly taken for seed, and never fails to give a luxuriant crop, provided it escape the following autumn. (Ibid.)
4865. Of the plants which the farmer has to choose for stock, the chief is the potato; and every one knows that no circumstances in the soil, climate, or culture will compensate for planting a bad sort. The potato requires a climate rather humid than otherwise, and rather moderate and equable in temperature than hot: hence the best crops are found in Lancashire, Dumfriesshire, and Ayrshire in Britain, and in Ireland, where the climate is very where moist. Excellently flavoured potatoes are also grown on mossy lands in most parts of the country. The prudent farmer will be particularly careful in choosing this description of plant stock, and also in changing it frequently, so as to ensure prolificacy and flavour. The general result of experience is decidedly in favour of Improved tubers for the purpose of propagation. A number of important papers on this subject will be found in the first and second volumes of the Gardener's Magazine, all confirming the advantages of selecting tubers which are immature.

Sect. III. Choice of Servants.

4866. On the moral and professional character of his servants much of the comfort of the farmer depends; and every one who has farmed near large towns, and at a distance from them, knows how great the difference is in every description of labourers. The servants required in farmeries are, the bailiff or head ploughman, common ploughmen, shepherds, labourers of all-work, herdsmen, and women. Sometimes apprentices and pupils are taken; but their labour is not often to be much depended on.

4867. A bailiff is required only in the largest description of farms, occupied by a professional farmer; and is not often required to act as market-man. In general young men are preferred, who look forward to higher situations, as gentlemen's bailiffs or land stewards. Most farmers require only a head ploughman, who works the best pair of horses, and takes the head of, and sets the example to, the other ploughmen in every description of work.

4868. Ploughmen should, if possible, be yearly servants, and reside upon the farm; if married, cottages should be provided for them. Weekly or occasional ploughmen are found comparatively unsteady; they are continually wandering from one master to another, and are very precarious supports of a tillage farm: for they may quit their service at the most inconvenient time, unless bribed by higher wages; and the farmer may thus lose the benefit of the finest part of the season. Where ploughmen and day labourers, however, are married, they are more to be depended upon than unmarried domestic servants, more especially when the labourer has a family, which ties him down to regular industry.

4869. The mode of hiring servants at what are called public statutes, so general in many parts of England, is justly reproved as having a tendency to vitiate their minds, enabling them to get places without reference to character, exposing good servants to be corrupted by the bad, promoting dissipation, and causing a cessation of country business for some days, and an awkwardness in it for some time afterwards. When hiring servants, it would be extremely important, if possible, to get rid of any injurious prepossessions, which are often prejudicial to the interests of the master, without being of any advantage to the servant. For instance, in Yorkshire and in other districts it is a custom to give farm servants liquor both morning and evening, whatever is the nature and urgency of the work. Nothing can be more absurd than permitting a ploughman to stop for half an hour in a winter day to drink ale, while his horses are neglected and shivering with cold.

4870. The following plan of maintaining the hinds or ploughmen in the best cultivated districts in Scotland, is found by experience to be greatly superior to any other mode hitherto adopted.

4871. Proper houses are built for the farm servants contiguous to every farmstead. This gives them an opportunity of adding to life, and of promoting their future welfare. Thus also the farmer has his people at all times within reach for carrying on his business.

4872. The farm servants, when married, receive the greater part of their wages in the produce of the farm, which gives them an interest in the prosperity of the concern in which they are employed, and in a manner obliges them to eat and drink comfortably; while young men often starve themselves in order to save money for drinking or clothes, in either of which cases they are deficient in the requisite animal strength. At least under this mode of payment they are certain of being supplied with the necessaries of life, and a rise of prices does not affect them; whereas, when their wages are paid in money, they are exposed to many temptations of spending it which their circumstances can ill afford, and during a rise of prices they are sometimes reduced to considerable difficulties. From the adoption of an opposite system, habits of sobriety and economy, so necessary in the servants of Scotland, and the advantages of which cannot be too highly appreciated, have arisen and still prevail in these districts.

4873. A most important branch of this system is, that almost every married man has a cow of a moderate size kept for him by the farmer all the year round. This is a boon of great utility to his family. The prospect of enjoying this advantage has an excellent effect upon the morals of young unmarried servants, who in general make it a point to lay up as much of their yearly wages as will enable them to purchase a cow and furniture for a house when they enter into the married state. These savings, under different circumstances, would most probably have been spent in dissipation.

4874. They have also several other perquisites, as a piece of ground for potatoes and flax (about one-eighth part of an acre for each); liberty to keep a pig, half a dozen hens, and bees; their fuel is carried home to them; they receive a small allowance in money per journey when sent from home with corn, or for seals or lime; and during the harvest they are maintained by the farmer, that they may be always at hand.
4875. There are nowhere to be met with more active, respectable, and conscientious servants than those who are kept according to this system. There is rarely an instance of their solicit ing relief from the public. They rear numerous families, who are trained to industry and knowledge in the operations of agriculture, and whose assistance in weeding the crops, &c. is of considerable service to the farmer. They become attached to the farm, take an interest in its prosperity, and seldom think of removing from it. Under this system every great farm is a species of little colony, of which the farmer is the resident governor. Nor, on the whole, can there be a more gratifying spectacle than to see a large estate under the direction of an intelligent landlord, or of an agent competent to the task of managing it to advantage; where the farms are of a proper size; where they are occupied by industrious and skilful tenants, anxious to promote, in consequence of the leases they enjoy, the improvement of the land in their possession; and where the cultivation is carried on by a number of married servants enjoying a fair competence and rearing large families, sufficient not only to replace themselves, but also, from their surplus population, to supply the demand and even the waste of the other industrious classes of the community. Such a system, there is reason to believe, is brought to a higher degree of perfection and carried to a greater extent in the more improved districts of Scotland than perhaps in any other country in Europe. (Code, &c.)

4876. A shepherd is of course only requisite on sheep farms; and no description of farm servant is required to be so steady and attentive. At the lambing season much of the farmer's property is in his hands, and depends on his unwarried exertions early and late. Such servants should be well paid and comfortably treated.

4877. The labourers required on a farm are few; in general, one for field operations, as hedge and ditch work, roads, the garden, cleaning out furrows, &c.; and another for attending to the cattle, pigs, and straw-yard, killing sheep and pigs when required, &c. will be sufficient. Both will assist in harvest, hay-time, threshing, filling dung, &c. These men are much better servants when married and hired by the year, than when accidental day labourers.

4878. The female servants required in a farmery are casual, as haymakers, turnip hoers, &c. or yearly, as house, dairy, and poultry maids. Much depends on the steadiness of the first class; and it is in general better to select them from the families of the married servants, by which means their conduct and conversation is observable by their parents and relations. A skilful dairy-maid is a most valuable servant, and it is well when the cattle-keeper is her husband; both may live in the farmer's house (provided they have no children), and the man may act as groom to the master's horse and chaise, and assist in brewing, butchery, &c. In the cheese districts, men often milk the cows, and manage the whole process of the dairy; but females are surely much better calculated for a business of so domestic a nature, and where so much depends on cleanliness.

4879. Farmer's apprentices are not common, but parish boys are so disposed of in some parts of the west of England, and might be so generally. They are said to make the best and steadiest servants; and indeed the remaining in one situation, and under one good master for a fixed period, say not less than three years, must have a great tendency to fix the character and morals of youth in every line or condition of life. (Apprentices intended for farmers are generally young men who have received a tolerable education beforehand, and have attained to manhood or nearly so. These pay a premium, and are regularly instructed in the operations of farming. We have already alluded to the example of Walker, who considers such apprentices, notwithstanding the care required to instruct them, rather useful than otherwise. (Hist. of Scot. vol. ii. p. 106.)

4881. To train ploughmen to habits of activity and diligence is of great importance. In some districts they are proverbial for the slowness of their step; which they teach their horses; whereas these animals, if accustomed to it, would move with as much ease to themselves in a quick as in a slow pace. Hence their ploughs seldom go above two miles in an hour, and sometimes even less; whereas, where the soil is light and sandy, they might go at the rate of three miles and a half. Farmers are greater sufferers than they imagine by this habitual indolence of their workmen, which extends from the plough to all their other employments, for it makes a very important difference in the expense of labour. (Code.)

**CHAP. IV.**

**General Management of a Farm.**

4882. The importance of an orderly systematic mode of managing every concern is sufficiently obvious. The points which chiefly demand a farmer's attention are the accounts of money transactions, the management of servants, and the regulation of labours.

**Sect. I. Keeping Accounts.**

4883. It is a maxim of the Dutch, that "no one is ever ruined who keeps good accounts," which are said in The Code of Agriculture to be not so common among farmers as they ought to be; persons employed in other professions being generally much more attentive and correct. Among gentlemen farmers there is often a systematic regularity in all their proceedings, and their pages of debtor and creditor, of expense and profit, are as strictly kept as those of any banking-house in the metropolis. But with the generality of farmers the case is widely different. It rarely happens that books are kept by
them in a minute and regular manner; and the accounts of a farmer, occupying even a large estate, and consequently employing a great capital, are seldom deemed of sufficient importance to merit a share of attention equal to that bestowed by a tradesman on a concern of not one-twentieth part of the value. There is certainly some difficulty in keeping accurate accounts respecting the profit and loss of so uncertain and complicated a business as the one carried on by the farmer, which depends so much on the weather, the state of the markets, and other circumstances not under his control; but the great bulk of farming transactions is settled at the moment; that is to say, the article is delivered and the money instantly paid; so that little more is necessary than to record these properly. In regard to the expenses laid out on the farm, an accurate account of them is perfectly practicable, and ought to be regularly attended to by every prudent and industrious occupier.

4884. To record pecuniary transactions is not the only object to be attended to in the accounts of a farmer. It is necessary to have an annual account of the live stock, and of their value at the time; of the quantity of hay un consumed; of the grain in store or in the stack-yard; and of the implements and other articles in which the capital is invested. An account, detailing the expense and return of each field, according to its productive contents, is likewise wanted, without which it is impossible to calculate the advantage of different rotations, the most beneficial mode of managing the farm, or the improvements of which it is susceptible. Besides the obvious advantages of enabling a man to understand his own affairs, and to avoid being cheated, it has a moral effect upon the farmer of the greatest consequence, however small his dealings may be. Experience shows that men situated like small farmers (who are their own masters, and yet have very little capital to manage or lose,) are very apt to contract habits of irregularity, procrastination, and indolence. They persuade themselves that a thing may be as well done tomorrow as today, and the result is, that the thing is not done till it is too late, and then hastily and imperfectly. Now nothing can be conceived better adapted to check this disposition than a determination to keep regular accounts. The very consciousness that a man has to make entries in his books of every thing that he does, keeps his attention alive to what he is to do; and the act of making those entries is the best possible training to produce active and pains-taking habits.

4885. Trotter's method of farm book-keeping. A very original, concise, and accurate mode of keeping farm accounts has been invented by Alexander Trotter, Esq of Dreghorn. Though the merits of this mode seem to be adhered to by all who understand it, yet they do not appear to be of that nature to bring it into general use. This, however, may depend partly, or even wholly, on the ignorance or prejudices of those for whom it is intended, and on the unfitness of farm managers for such regular and multiplied entries of all their transactions as this system requires. We regret that Mr. Trotter's method has not attracted more notice from scientific farmers. We would recommend to them his " Method of Farm Book-keeping, &c. exemplified by the Forms and Accounts actually practised by the Author in the management of his Farm at Colinton, near Edinburgh." Edin. 1825." The books and forms of Mr. Trotter's Method may be got by applying at Messrs. Kirkton's, stationers, No. 1. Portland-street, London; or at Mr. Abraham Thomson's, bookbinder, Old Fishmarket, Edinburgh.

4886. The accounts of gentlemen farmers, or of the bailiffs they employ, it is said in The Code, cannot be too minute; but in regard to rent-paying farmers the great objects are to have them short and distinct. For this purpose a journal for business transactions, such as purchases, sales, agreements, hireings, and other real or prospective arrangements, a cash-book and a ledger will, in our opinion, be sufficient, with the aid of memorandum books. But for greater accuracy, or rather for more curious farmers, the following models are given in The Code of Agriculture. The gentleman farmer and bailiff will find various descriptions of "Farmer's account books" among the booksellers. One in very general use is Harding's Farmer's Account Book.

4896. *These forms* may be useful, by directing the attention of farmers to the particulars of which they should keep an accurate record; but as to any particular system of accounts applicable to farmers a good deal of delusion seems to prevail, as if the established modes in general use among mercantile men would not answer. In fact, there is no correct mode of keeping accounts but by the principles of double entry.

4897. *The account books for a common farmer* may be, a cash-book for all receipts and payments, specifying each; a ledger for accounts with dealers and tradesmen; and a stock book for taking, once a year, an inventory and valuation of stock, crop, manures, tillages, and every thing that a tenant could dispose of or be paid for on quitting his farm. Farming may be carried on with the greatest accuracy and safety, as to money matters, by means of the above books, and a few pocket memorandum books for labourers' time, jobs, &c. With the exception of a time-book, such as we have before described (3883), we should never require more, even from a proprietor's bailiff; many of whom the nine forms just given (4887) would only puzzle, and some we have known them lead to the greatest errors and confusion. Munro's *Guide to Farm Book-keeping* (Edin. 12mo. 1821) may be recommended to the practical farmer; but no form of books, or mode of procedure will enable a farmer to know whether he is losing or gaining but that of taking stock.

4898. *A form for a cattle stock account* has been recommended by Sir Patrick Murray, of which it may be useful to present a specimen. This form, Sir Patrick observes, has been kept at his estate of Ochtertyre, in Perthshire, for twenty-two years, and found perfectly adapted to the purpose in view; being sufficiently simple in form to be understood by every farm manager, and sufficiently comprehensive in particulars to embrace all the requisite details. They may be either made up quarterly, half-yearly, or yearly. Sir Patrick adopts the half-yearly mode.

In former times, farm servants lived at the same table with their masters, and that is still the practice in those districts where the farms are small. On moderate-sized, and on large farms, they are usually sent to a separate table; but of late a custom has been introduced of putting them on board-wages. This is a most pernicious practice; which often leads them to the ale-house, corrupts their morals, and injures their health. It is a better plan, with a view of lessening trouble, to board them with the bailiff; but it is still more desirable for the farmer to have them under his own eye, that he may attend to their moral conduct. He will find much more useful assistance from the decent and the orderly than from the idle and the profiteer.

The best mode of managing yearly married servants, whether ploughmen or labourers, we conceive to be that already referred to (4870) as practised in Northumberland, and other northern counties. Marshal (Review of Bailey's Northumberland) calls it a remain of feudal times; but certainly, if it be so, it appears one of those remains which should be carefully preserved. We may challenge the empire to produce servants and farm operations equal to those where this system is adopted. The great excellence of the system consists on its being founded in the comfort of the servant.

The permanent labourers on a farm ought to be treated in the same manner as the ploughmen; and indeed it is much to be wished, for the sake both of humanity and morality, that all married labourers, who live in the country, should have gardens attached to their cottages, if not a cow kept, and a pig and fowls, in the manner of the Scottish ploughmen. Some valuable observations on this subject will be found in The Husbandry of Scotland.

Temporary labourers, or such as are engaged for hay-making, reaping, turnip-hoeing, &c. are for the most part beyond the control of the farmer, as to their living and lodging. It is a good practice, however, where hay-making and reaping are performed by the day, to feed the operators, and to lodge on the premises such of them as have not homes in the neighbourhood; providing them with a dry loft and warm blankets. Piece or job-work, however, is now becoming so very general, in all farm operations performed by occasional labourers, that attention to these particulars becomes unnecessary, and the farmer's chief business is to see that the work be properly done.

A day's work of a country labourer, is ten hours during the spring, summer, and autumn quarters. Farmers, however, are not at all uniform in their hours of working during these periods. Some begin at five o'clock, rest three hours at midday, during the more violent heat of the sun, and fill up their day's work by beginning again at one o'clock, and ending at six in the evening. Others begin at six, and end at six, allowing half an hour at breakfast, and an hour at dinner. But although these are the ordinary hours, both for servants and labourers, during the more busy seasons of the year, yet neither of them will scruple to work either sooner or later, when occasion requires. In regard to the winter months, the hours of labour are from the dawn of morning, as long as it is light, with the allowance of about half an hour at midday for dinner.

That the rate of labour must in a great measure depend upon the price of grain, is a general principle. In England, the value of a peck of wheat, and in Scotland, of a peck of oatmeal (being the principal articles of subsistence of the lower orders of the people in the two countries), were long accounted an equivalent to the daily pay of a labourer. In both countries, however, the price of potatoes has, of late years, had a considerable influence on the rate of labour; and in England, the effects of the poor laws have tended to keep down that rate below the increased price of provisions, and thus have deranged the natural progress of things. It has been ascertained, that a man, his wife, and from two to three children, if wheat is their habitual food, will require ten gallons weekly. When they live on bread, hard-working people ought to have the best kind, as that will furnish the most nutrition. How, then, could a labourer and his family exist upon wages of from 6s. to 9s. per week, when wheat is from 8s. to 10s. or 12s. per bushel? The difference is compensated by the poor-rates, a most exceptionable mode of making up the deficiency; for labour would otherwise have found its own level, and the labourer would have obtained the price of a bushel and a half of wheat weekly.

In Scotland, the rate of labour has increased beyond the price of provisions. Prior to 1792, the average price of a peck of oatmeal was 1s. 1d., and the average price of a day's labour in summer 1s. 1d., which nearly corresponded with the principle above stated: but the average price of a peck of oatmeal in 1810 was 1s. 3½d., whilst the average price of a day's labour was 1s. 1½d., which shows, in a most satisfactory manner, the very great improvement that has taken place in the lot of the labouring classes in that part of the United Kingdom. (Gen. Rep. vol. iii. p. 362.)

The practice of giving labourers grain, &c. at a cheap rate was adopted by George 111., who carried on farming operations to a considerable extent, allowing his labourers flour at a fixed price, whatever wheat might sell for. This benevolent system has been practised by several gentlemen farmers, some of whom have allowed bread, and others a daily quantity of milk, at moderate prices. The same system is general in several of the western counties, as in Dorset, Devon, and Cornwall, where the labourers have a standing supply of bread-corn; of wheat at 6s. and of barley at 5s. per bushel. In some of the midland
counties the day wages are regulated by the price of the best wheaten bread: thus the price of a half-peck leaf corn forms the wages for out-door farm servants. Of late years this rule has been departed from in favour of the labourers: thus, when bread is at 1s. Sly the half-peck, then wages are 1s. 10d.; and when at 2s., the wages are 2s. 4d.

4908. Most descriptions of country labour, performed without the aid of horses, may be let by the job. Farey, in his excellent Report of Derbyshire, informs us, that besides all ordinary labour, the late John Billingsley, of Ashwick Grove, in Somersetshire, let his ploughing, harrowing, rolling, sowing, turning of corn with cut, hay-making, &c., by the acre; from which he found great advantages, even where his own oxen and horses were used by the takers of the work. Whether we regard despatch, economy, perfection of rural works, or the bettering of the condition of the labourers therein, nothing will contribute so much to all these as a general system of letting works at fair and truly apportioned prices, according to the degree of labour and skill required in each kind of work. Few persons have doubted that despatch and economy are attainable by this method; but those who have indolently or improperly gone about the letting of their labour, have uniformly complained of its being slowly done, and of the promeness of the men to cheat when so employed. Such frauds are to be expected in all modes of employment, and can only be counteracted, or made to disappear, by competent knowledge and due vigilance in the employer, or his agents and foremen, who ought to study and understand the time and degree of exertion and skill, as well as the best methods, in all their minutiae, of performing the various works they have to let. At first sight these might seem to be very difficult and unattainable qualifications in farmers' bailiffs or foremen, but it is nevertheless certain, that a proper system and perseverance will soon overcome these difficulties. One of the first requisites is, the keeping of accurate and methodical day-accounts of all men employed; and, on the measuring up and calculating of every job of work, to register how much has been earned per day, and never to attempt abatement of the amount, should this even greatly exceed the ordinary day's pay of the country; but let this experience gained operate in fixing the price of the next job of the same work, in order to lessen the earnings by degrees, of fully competent and industrious men, to 1½ or 1¾ times the ordinary wages when working by the day.

4909. Form the men into small gangs, according to their abilities and industry, and always set the best gang about any new kind of work, or one whose prices want regulating: encourage these by liberal prices at first, gradually lowering them, and laying them on at work with or near them at the same kind of work. On the discovery of any material slight of or deception in the work, at the time of measuring it, more than their proportionate values should be deducted for them, and a separate job made to one of the best gangs of men, for completing or altering it: by which means shame is made to operate, with loss of earnings, in favour of greater skill, attention, and honesty in future. When the necessity occurs of employing even the best men by the day, let the periods be as short as possible, and the prices considerably below job earnings; and contrive, by the offer of a desirable job to follow, to make it their interest and wish to despatch the work that is necessary to be done by the day, in order to get again to piece-work. The men being thus induced to study and contrive the readiest and best methods of performing every part of their labour, and of expediting their time, the work will be done the better and cheaper than by the thoughtless drones who usually work by the day. And that these are the true methods of bettering the condition of the labourers, Malthus has ably shown in theory; and all those who have adopted and persevered in them have seen the same in practice. (Farey's Derbyshire, vol. iii. 192.)

Sect. III. Arrangement of Farm Labour.

4910. The importance of order and system we have already insisted on (3370), and the subject can hardly be too often repeated. To conduct an extensive farm well is not a matter of trivial moment, or one to the management of which every man is competent. Much may be effected by capital, skill, and industry; but even these will not always ensure success without judicious arrangement. With it, a farm furnishes an uninterrupted succession of useful labour during all the seasons of the year; and the most is made that circumstances will admit of, by regularly employing the labouring persons and cattle, at such works as are likely to be the most profitable. Under such a system it is hardly to be credited how little time is lost, either of the men or horses, in the course of a whole year. This is a great object; for each horse may be estimated at three shillings per day, and each man at two shillings. Every day, therefore, in which a man and horse are unemployed occasions the loss of at least five shillings to the husbandman.

4911. As the foundation of a proper arrangement, it is necessary to have a plan of the farm, or at least a list of the fields or parcels of land into which it is divided, describing their productive extent, the quality of the soil, the preceding crops, the cultivation given to each, and the species and quantity of manure they have severally received. The future treatment of each field, for a succession of years, may then be resolved on with more probability of success. With the assistance of such a statement, every autumn an arrangement of crops for the ensuing year ought to be made out; classing the fields or pieces of land, according to the purposes for which they are respectively intended. The number of acres allotted for arable land, meadow, or pasture, will thus be ascertained. It will not then be difficult to discover what numbers of horses and labourers will be
required during the season for the fields in culture, nor the live stock that will be necessary for the pasture land. The works of summer and harvest will likewise be foreseen, and proper hands engaged in due time to perform them.

4912. A farmer should have constantly in view a judicious rotation of crops, according to the nature and quality of his soil, and should arrange the quantity and succession of labour accordingly. Team labour, when frost and bad weather do not interfere, should be arranged for some months; and hand labour, for some weeks, according to the season of the year. "A general memorandum list of business to be done," may therefore be useful, that nothing may escape the memory, and that the most requisite work may be brought forward first, if suitable to the state of the weather. In this way the labour will go on regularly, and without confusion; while, by a proper attention, either a distribution of labour, or an occasional consolidation of it, may be applied to every part of the farm.

4913. As general rules, connected with the arrangement, and the successful management of a farm, the following are particularly to be recommended:—

4914. The farmer ought to rise early, and see that others do so. In the winter season breakfast should be taken by candle-light, for by this means an hour is gained which many farmers indolently lose; though six hours in a week are nearly equal to the working part of a winter day. This is a material object, where a number of servants are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.

4915. The whole farm should be regularly inspected, and not only every field examined, but every beast seen, at least once a day, either by the occupier, or by some intelligent servant.

4916. In a considerable farm, it is of the utmost consequence to have servants specially appropriated for each of the several departments. For their work and that of labour-time, where persons are frequently changing their employments. Besides, where the division of labour is introduced, work is executed not only more expeditiously, but also much better, in consequence of the same hands being constantly employed in one particular department. For that purpose, the ploughmen ought never to be employed in manual labour, but regularly kept at work with their horses, when the weather will admit of it.

4917. To arrange the operation of ploughing, according to the soils cultivated, is an object of essential importance. On many farms, the different soils which are sooned and untilled aresubjected to severe drought. In such cases, the prudent farmer, before the wet season commences, should plough such land as in the greatest danger of being injured by too much wet; and before the dry period of the year sets in, he should till such land as in the greatest danger of being rendered unfit for ploughing by too much drought. The season between seed-time and harvest may be well occupied in working soils intended to be sown with beans, oats, barley, and other spring crops. On farms where rules are attended to there is always some land in a proper condition to be ploughed, or to be worked by the improved harrows or grubbers; and there is never any necessity either for delaying the work, or performing it imperfectly.

4918. Every means should be thought of to diminish labour, or to increase its power. For instance, by proper arrangement, five horses may do as much labour as six perform, according to the usual mode of employing them. The horse may be employed in caring turnips during winter, or in other necessary farm work at other seasons, without the necessity of reducing the number of ploughs. When driving dung from the farm-yard, three carts may be used, one always filling in the yard, another going to the field, and a third revolution; the leading horse of the empty cart ought then to be yoked, and put to the full one. In the same manner, while one pair of horses are preparing the land for sowing turnips, the other three horses may be employed in carrying the dung to the land, either with two or three carts, as the situation of the ground may happen to require. By extending the same management to other farm operations, considerable saving of labour may be effected.

4919. Previously to engaging in a work, whether of ordinary practice, or of intended improvement, the best consideration of which the farmer is capable ought to be given to it, till he is satisfied that it is advisable for him to attempt it. When begun, he ought to proceed in it with much patience and perseverance, until he has given it a fair trial. It is a main object, in carrying on improvements, not to attempt too much at once; and never to begin a work without a probability of being able to finish it in due season.

4920. By the adoption of these rules, every farmer will be master of his time, so that every thing required to be done will be performed at the proper moment, and not delayed till the season and opportunity have been lost. The impediments arising from bad weather, sick servants, or the occasional and necessary absence of the master, will, in that case, be of little consequence, nor will they embarrass the operations to be carried on; and the occupier will not be prevented from attending to even the smallest concerns connected with his business, on the aggregate of which his prosperity depends.

Sect. IV. Domestic Management and Personal Expenses.

4921. On domestic affairs a hint may suffice. Young farmers beginning housekeeping, like most others in similar circumstances, are apt to sink too great a proportion of their capital in furniture, and furnishing riding-horses, carriages, &c.; and sometimes to live up to, or even beyond, their income. We do not mean that farmers should not live as well as other men of the same property; but merely that all beginners should live within their income. Even in the marketing expenses care is requisite; and the prudent farmer will do well, every penny or sixpence he lays out, to reckon up in his mind what that sum per day would amount to in a year. The amount will often astonish him, and lead to economy and, where practicable, retrenchment. Saving, as Franklin has inculcated, is the only certain way of accumulating money.

4922. In regard to housekeeping, it is observed in The Code of Agriculture, that the safest plan is, not to suffer it to exceed a certain sum for bought articles weekly. An annual sum should be allotted for clothing, and the personal expenses of the farmer, his
wife and children, which ought not to be exceeded. The whole allotted expense should be considerably within the probable receipts; and, if possible, one eighth of the income annually received should be laid up for contingencies, or expended in extra improvements on the farm.

BOOK VI.

CULTURE OF FARM LANDS.

4923. The business of farming consists of the culture of vegetables, and the treatment or culture of animals; in practice these are generally carried on together, but may be more conveniently treated of apart. In this Book, therefore, we confine ourselves to the culture of vegetable, and shall consider in succession the general processes of culture; the culture of corn and pulse; of roots and leaves; of herbage plants; of grasses; and of manufactorial plants.

CHAP. I.

General Processes common to Farm Lands.

4924. Among general processes, those which merit particular notice in this place are, the rotation of crops, the working of fallows, and the management of manures. The theory of these processes has been already given in treating of soils and manures (Part II. Book III.); and it therefore only remains to detail their application to practice under different circumstances.

SECT. I. Rotation of Crops suitable to different Descriptions of Soils.

4925. The proper distribution of crops, and a plan for their succession, is one of the first subjects to which a farmer newly entered on a farm requires to direct his attention. The kind of crops to be raised are determined in a great measure by the climate, soil, and demand, and the quantity of each by the value, demand, and the adjustment of farm labour.

4926. In the adjustment of farm labour, the great art is to divide it as equally as possible throughout the year. Thus it would not answer in any situation to sow exclusively autumn crops, as wheat or rye; nor only spring corns, as oats or barley; for by so doing all the labour of seed-time would come on at once, and the same of harvest work, while the rest of the year there would be little to do on the farm. But by sowing a portion of each of these and other crops, the labour both of seed-time and harvest is divided and rendered easier, and is more likely to be done well and in season. But this point is so obvious as not to require elucidation.

4927. The succession or rotation of crops is a point on which the profits of the farmer depend more than on any other. It is remarked by Arthur Young, that agricultural writers, previously to the middle of the eighteenth century, paid little or no attention to it. They recite, he says, courses good, bad, and execrable in the same tone, as matters not open to praise or censure, and unconnected with any principles that could throw light on the arrangement of fields. The first writer who assigned due importance to the subject of rotations seems to have been the Rev. Adam Dickson, in his Treatise on Agriculture, published in Edinburgh in 1777; and soon afterwards Lord Kaimes, in his Gentleman Farmer, illustrates the importance of the subject: both writers were probably led to it by observing the effects of the Norfolk husbandry, then beginning to be introduced to Berwickshire. But whatever may have been the little attention paid to this subject by former writers, the importance of the subject of rotations, and the rule founded on the principles already laid down, that culmiferous crops ripening their seeds should not be repeated without the intervention of pulse, roots, herbage, or fallow, is now "recognised in the practice and writings of all judicious cultivators, more generally perhaps than any other." (Edit. of Farmer's Mag.)

4928. The system of rotations is adapted for every soil, though no particular rotation can be given for any one soil which will answer in all cases; as something depends on climate, and something also on the kind of produce for which there is the greatest market demand. But wherever the system of rotations is followed, and the several processes of labour which belong to it properly executed, land will rarely get into a foul and exhausted state, or, at least, if foul and exhausted under a judicious rotation, "matters would be much worse were any other system followed."

4929. The particular crops which enter into a system of rotation must obviously be such as are suited to the soil and climate, though, as the experienced author so often quoted observes, "they will be somewhat varied by local circumstances, such as the proximity of towns and villages, where there is a greater demand for turnips, potatoes, bar, &c. than in thinly peopled districts. In general, beans and clover, with ryegrass, are interposed between corn crops on clayey soils; and turnips, potatoes, and clover with ryegrass on dry loams and sands, or what are technically known by the name of turnip soils. A variety of
other plants, such as peas, tares, cabbages, and carrots, occupy a part, though commonly but a small part, of the land, and all of a farm which is allotted to green crops. This order of succession is called the system of alternate husbandry; and on rich soils, or such as have access to abundance of putrescent manure, it is certainly the most productive of all others, both for food for man and for the inferior animals. One half of the farm is left fallow in this course always under some of the different species of cereal grasses, and the other half under pulse, roots, cultivated herbage, or plain fallow.

4930. But the greater part of the arable land of Britain cannot be maintained in a fertile state under this management; and sandy soils, even though highly manured, either are not suitable for cultivation or become necessary to leave that division or break that carries cultivated herbage to be pastured for two years or more, according to the degree of its consistency and fertility; and all the fields of a farm are treated thus in their turn if they require it. This is called the system of continuous husbandry, a regular change being constantly going on from aration to pasturage, and vice versa.

4931. Not to repeat the same kind of crop at too short intervals, is another rule with regard to the succession of crops. Whatever may be the cause, whether it is to be sought for in the nature of the soil or of the vegetation itself, or in the experience of the experiment, it proves the advantages of introducing a diversity of species into every course of cropping. When land is pastured several years before it is brought again under the plough, there may be less need for adhering steadily to this rule; but the degeneracy of wheat and other crops, and of the same crop, when the same is repeated year after year, for a long period, hath been sufficiently known. It is the same with what are called green crops; beans and peas, potatoes, turnips, and in an especial manner red clover, become all of them much less productive, and much more liable to disease, when they come into the course, upon some land, every second, third, or fourth year. But what the interval ought to be has not yet been ascertained, and, from the great number of years that experiments must be continued to give any certain result, probably cannot be determined until the component parts of soils, and particularly the sort of vegetable nourishment which each species of plant extracts from the soil, have been more fully investigated.

4932. A change of variety as well as of the species, and even of the plants of the same variety, is found to be attended with advantage; and in the latter case, or a change of seed, the species and variety being the same, the practice is almost universally adopted. It is well known, that of all the cultivated species, as much as is possible, one which had grown on a soil differing much from that on which it is to be sown, will yield a better produce than the other that grew in the same or a similar soil and climate. The farmers of Scotland accordingly find that wheat from the south, even though it be not, as it usually is, of a particular variety, when sown on a clayey or a sandy soil, other things being equal, are more productive than such as have grown on sandy soil. (Supp. Encyc. Brit. art. Agr. 114.)

4933. The following are examples of rotations suited to different soils, as given in Brown's excellent Treatise on Rural Affairs. The basis of every rotation, he says, "we hold to be either a bare summer fallow, or a fallow on which drilled turnips are cultivated, and its conclusion to be with the crops taken in the year preceding a return of fallow or drilled turnips, when of course a new rotation commences.

4934. Rotation for strong deep lands. According to this rotation, wheat and drilled beans are the crops to be cultivated, though clover and rye-grass may be taken for one year in place of beans, should such a variety be viewed as more eligible. The rotation begins with summer fallow, because it is only on strong deep lands that it may go, and it is of sufficient length of time to permit the land to be kept clean, though it ought to stop the moment that the land enters a contrary condition. A considerable quantity of manure is required to go on successfully; perhaps dung should be given to each bean crop; and if this crop is drilled and attentively horse-hoed, the rotation may turn out to be one of the most profitable that can be exercised.

4935. Rotation for loams and clays. Where it may not be advisable to carry the first rotation into execution, a different one can be practised, according to which labour will be more divided, and the usual grains more generally cultivated; for instance, the following, which is used to be common in East Lothian;

1. Fallow, with dung.
2. Wheat.
5. Clover and rye-grass.
6. Oats or wheat.

This rotation is excellently calculated to insure an abundant return through the whole of it, provided dung is applied upon the clover; and, though it is divided, the crops of the preceding year is kept clean, and it continues to the next two years of the rotation, when it is commenced.

4936. Rotation for cloays and inferior description. This rotation is calculated for soils of an inferior description to those already treated of.

1. Fallow, with dung.
2. Clover and rye-grass.
3. Wheat.
5. Oats.

According to this rotation, also in use in East Lothian, the rules of good husbandry are indispensably practised; while the sequence is obviously calculated to keep the land in good order, and in such a condition as to ensure crops of the greatest value. If manure is bestowed either upon the clover-stubble or before the beans are sown, the rotation is one of the best that can be devised for the soils mentioned.

4937. Rotation for thin clays. On thin clays gentle husbandry is indispensably necessary, otherwise the soil may be exhausted, and the produce unequal to the expense of cultivation. Soil of this description will not improve much from manure, and additional means must be procured for retaining and restoring them in that way, even though the produce should in the mean time be comparatively of small value. The following rotation is not an improper one:

1. Fallow, with dung.
2. Clover and rye-grass.
3. Wheat.
4. Grass pastured, but not too early eaten.
5. Grass.
6. Oats.

This rotation may be shortened or lengthened, according to circumstances, but should never extend further in point of ploughing than when dung can be given to the fallow-break. This is the best course of the whole; and if neglected the rotation is rendered useless.

4938. Rotation for peat earth soils. These are not friendly to wheat, unless aided by a quantity of calculated manure, in order to stimulate them in a general point of view, it is not advisable to cultivate wheat, but a crop of oats may be almost depended upon, provided the previous management has been judiciously executed. If the subsoil of peat earth lands is retentive of moisture, the process ought to commence with a barley crop, so that, such a small amount of free and open-bottomed, a crop of turnips may be substituted for fallow; according to which method, the surface will get a body which naturally it did not possess. Grass on such soils must always occupy a great space of every rotation, because physical circumstances render regular cropping utterly impracticable.

1. Fallow, or turnips with dung.
2. Oats of an early variety.
3. Clover, and a considerable quantity of perennial rye grass.
4. Pasture for several years, till circumstances permit the land to be broken up, when oats are to be repeated.
4939. Rotation for light soils. These are easily managed, though to procure a full return of the profit which they are capable of yielding, requires generally as much attention as is necessary in the manage-
ment of those of a stronger description. Upon light soils, a bare summer fallow is seldom called for, as
cleanness may be preserved by growing turnips, and other leguminous articles. Grass also is of emi-
nect advantage upon such soils, often yielding a greater profit than what is afforded by culmiferous
rods.

1. Turnips.
2. Spring wheat, or barley.
3. Clover and ryegrass.
4. Oats or wheat.

This is a fashionable rotation; but it may be doubted whether a continuance of it for any considerable
period is advisable, because both turnips and clover are found to fall off when repeated so often as once in
four years. Common red clover will not grow every four years, unless guypsum be restored to the land.
Perhaps the rotation would be greatly improved were it extended to eight years, whilst the ground, by such
an extension, would be kept fresh and constantly in good condition. As, for instance, were seeds for pas-
ture sown in the second year, the ground kept three years under grass, broke up for oats in the sixth year,
drilled with beans and peas in the seventh, and sown with wheat in the eighth; the rotation would then
be complete, because it included every branch of husbandry, and admitted a variety in management gene-
rously agreeable to the soil, and always favorable to the interest of cultivators. The rotation may also con-
sist of six crops, were the land kept only one year in grass, though few situations admit of so much
cropping, unless additional manure is within reach.

4940. Rotation for sandy soils. These, when properly manured, are well adapted to turnips, though it
rarely happens that wheat can be cultivated on them with advantage, unless they are dressed with alluvial
compost, marl, clay, or some such substances as will give a body or strength to them, which they do not
naturally possess. Barley, oats, and rye, the latter especially, are, however, sure crops on sands, and in
favorable seasons will return greater profit than can be obtained from wheat.

1. Turnips well manured consumed on the ground.
2. Barley sown with clover and ryegrass.
3. Clover and ryegrass.
4. Wheat, rye, or oats.

By keeping the land three years in grass, the rotation would be extended to six years, a measure highly
advisable.7

4941. These examples are sufficient to illustrate the subject of improved rotations; but the best gen-
eral schemes may be sometimes momentarily deviated from with advantage, the same able author adds, that "cross cropping, in some cases, may perhaps be justifiable in practice; as, for instance, we have seen wheat taken after oats with great
success, when these oats had followed a clover crop on rich soil; but, after all, as a general measure, that mode of cropping cannot be recommended. We have heard of another rotation, which comes almost like the predicament, though, as the test of experience has not yet been applied, a decisive opinion cannot be pronounced upon its
merits. This rotation begins with a bare fallow, and is carried on with wheat, grass for one year or more, oats, and wheat, where it ends. Its supporters maintain that beans are an uncertain crop, and cultivated at great expense; and that in no other way will corn, in equal quantity and of equal value, be cultivated at so little expense as according to the plan mentioned. That the expense of cultivation is much lessened, we acknow-
ledge, because no more than seven ploughings are given through the whole rotation; but whether the crops will be of equal value, and whether the ground will be preserved in equally good condition, are points which remain to be ascertained by experience." (Brown on Rural Affairs.)

4942. As a general guide to devising rotations on clay soils, it may be observed, that winter or autumn sown crops are to be preferred to such as are put in in spring. Spring ploughing on such soils is a hazardous business, and not to be practised where it can possibly be avoided. Except in the case of drilled beans, there is not the slightest necessity for ploughing clays in the spring months; but as land intended to carry beans ought to be early ploughed, so that the benefit of frost may be obtained, and as the seed furrow is an ebb one, rarely exceeding four inches in depthness, the hazard of spring ploughing for this article is not of much consequence. Ploughing with a view to clean soils of the description under consideration has little effect, unless given in the summer months. This renders summer fallow indispensably necessary; and without this radical process, none of the heavy and wet soils can be suitably managed, or preserved in a good condition.

4943. To adopt a judicious rotation of cropping for every soil, requires a degree of judgment in the farmer, which can only be gathered from observation and experience. The old rotations were calculated to wear out the soil, and to render it unproductive. To take wheat, barley, and oats in succession, a practice very common thirty years ago, was sufficient to impoverish the best of land, while it put little into the pockets of the farmer; but the modern rotations, such as those which we have described, are founded on principles which ensure a full return from the soil, without lessening its value, or impoverishing its condition. Much depends, however, upon the manner in which the different processes are executed; for the best arranged rotation may be of no avail, if the processes belonging to it are imperfectly and unseasonably executed. (See 2221.) The best farmers in the northern counties now avoid over-cropping or treating land in any way so as to exhaust its powers, as the greatest of all evils.

Sect. II. The working of Fallows.

4914. The practice of falling, as we have seen in our historical view of Greek and Roman agriculture, has existed from the earliest ages; and the theory of its beneficial
effects we have endeavoured to explain. (2175.) The Romans with their agriculture introduced fallows in every part of Europe; and two crops, succeeded either by a year's fallow, or by leaving the land to rest for two or more years, became the rotation on all soils and under all circumstances. This mode of cultivating arable land is still the most universal in Europe, and was prevalent in Britain till the middle of the last century; but as a crop was lost every year they occurred, a powerful aversion from naked fallows arose about that time, and called for numerous attempts to show that they were unnecessary, and consequently an immense public loss. This anti-fallowing mania, as it has been called, was chiefly supported by Arthur Young, Nathaniel Kent, and others, members or correspondents of the Board of Agriculture: it was at its greatest height about the beginning of the present century, but has now spent its force; and after exhausting all the arguments on both sides, as an able author has observed, “the practice does not appear to give way, but rather to extend.”

4915. The expediency or inexpediency of pulverising and cleaning the soil by a bare fallow, is a question that can be determined only by experience, and not by argument. No reasons, however ingenious, for the omission of this practice, can bring conviction to the mind of a farmer, who, in spite of all his exertions, finds, at the end of six or eight years, that his land is full of weeds, sour, and comparatively unproductive. Drilled and horse-hoed green crops, though cultivated with advantage on almost every soil are probably in general unprofitable as a substitute for fallow, and after a time altogether inefficient. It is not because turnips, cabbages, &c. will not grow in such soils, that a fallow is resorted to, but because, taking a course of years, the value of the successive crops is found to be so much greater, even though an unproductive year is interposed, as to induce a preference to fallowing. Horse-hoed, crops of beans in particular, postpone the recurrence of fallow, but a few situations can ever exclude it altogether. On the other hand, the instances which have been adduced, of a profitable succession of crops on soils of this description, without the intervention of a fallow, are so well authenticated, that it would be extremely rash to assert that it can in no case be dispensed with on clay soils. Instances of this kind are to be found in several parts of Young's Annals of Agriculture; and a very notable one, on Greg's farm of Coles, in Hertfordshire, is accurately detailed in the sixth volume of The Communications to the Board of Agriculture.

4916. The principal causes of this extraordinary difference among men of great experience, may probably be found in the quality of the soil, or in the nature of the climate, or in both. Nothing is more vague than the names by which soils are known in different districts. Greg's farm, in particular, though the soil is denominated “heavy arable land,” and “very heavy land,” is found so suitable to turnips, that a sixth part of it is always under that crop, and these are consumed on the ground by sheep; a system of management which every farmer must know to be altogether impracticable on the wet tenacious clays of other districts. It may indeed be laid down as a criterion for determining the question, that wherever this management can be profitably adopted, fallow, as a regular branch of the course, must be not less absurd than it is injurious, both to the cultivator and to the public. It is probable, therefore, that, in debating this question about the quality of the land, and, it may be added, the property of absorbing and retaining moisture, soils different in that soil in common language have the same denomination.

4917. Another cause of difference must be found in the climate. It is well known that a great deal more rain falls on the west than on the east coast of Britain; and that between the northern and southern counties there is at least a month or six weeks' difference in the maturation of the crops. Though the soil, therefore, be as nearly as possible similar in quality and surface, the period in which it is accessible to atmospheric influence, is much different. The northern counties, in the south of England, wheat is rarely sown before December; whereas in the north, and still more in Scotland, it cannot be sown at the end of September, though the farmers of the north are exclusively employed in harvest work, which is frequently not finished by the beginning of November. In some districts in the south of England, wheat is really sown from May. All the crops, and all the modes of management which have been proposed as substitutes for fallow, are well known to such men, and which unquestionably have been generally adopted long ago, if, upon a careful consideration of the advantages and disadvantages on both sides, a bare fallow was found to be unprofitable. Some persons wish to examine the question fairly and impartially, and many others, the following: — Young's Annals of Agriculture, and his writings generally; Hunter's Geographical Essays; Dickson's Practical Agriculture; Sir H. Davy's Agricultural Chemistry; The Agriculture Newspaper Committee on Rural Improvements; The County Reports; The General Report of Scotland, and the Quarterly Journal of Agriculture, vol. ii. p. 90.

4918. The importance of naked fallows has been ably pointed out by a writer in the work last referred to. "In order," he says, "to show more forcibly the difficulty of cleaning heavy lands for green crops, let us take a review of the time of the year in which these crops should be sown. In clay lands, beans must be sown in March at latest, and before that period of the year no one can pretend to clean land at all. Finding it impossible to use them as a fallow crop, they are sown without dung on the land, and which, where it is of light lands, be much straw without manure, and their utility as a crop in the rotation is, of course, thereby much decreased on such soils; and if they are to be sown as a fallow crop with dung on the land that is to be appropriated to fallow, they give much less time for the preliminary cleaning of the land than turnips can be sown. In clay and other soils, the same observations will, therefore, apply to them as to beans as a cleaner of the land. It is only from their great value as human food, and from their inability to grow without dung, that they are important; as a preventive of weeds, they are inconsiderable to keep them under; and when the soil is thoroughly clean, under a potato fallow. Thus there is difficulty in cleaning land, without summer fallow, with beans and potatoes on every kind of soil in any spring, however favourable; and it is quite impossible to do so in a wet one. There is also difficulty in cleaning strong clay land even by turnip-tine in May; and
and, of course, no system of keeping land clean but without the assistance of bare fallow. But even this substitution is only an approximation to cleanliness; for every one knows, who has farmed light soils for a series of rotations, whatever his practice may be, that even the turnip crop cannot do more to keep the land clean than without the aid of grass—old or new, and knot grass; and no better mode of extinguishing these formidable robbers of the artificial nourishment of the cultivated crops, than by bare following, has yet been discovered. They are the roots of the soil. Indeed, the practice of the best farmers of light land, however great their desire to cultivate the land with as much thoroughness as possible, is to have the land under grass the greater part of the time, and to cultivate only under the extent of it may no doubt be limited by the want of manure, from a desire to keep their land clean; and this is accomplished by summer following that portion of it which had carried potatoes in the preceding rotation, and raising the potatoes and turnips in that part of the year in which they had been previously grown. This is a good practice, not only as a means of keeping land clean, but as following out that system of alternate husbandry of white and green crops, which has, by abolishing a succession of white crops with their scouring effects, toned more than any other to render the land more wholesome, and thus more fertile. But such thoughts often prevail over better knowledge; and they furnish no argument in favour of cleanliness. But such thoughts display, in their effects, great negligence and ignorance: negligence, in permitting any weeds to cover the land, particularly the root-grown crops, by which the strength of the soil is exhausted, and in losing the most favourable part of the year, to make up their deficiency for which; and ignorance, in failing to afford nourishment to the soil, that when soil has been exhausting itself in bearing the crop of weeds. These facts are which are known to every practical farmer, and the nature of which presses upon him a conviction of the necessity of summer following more strongly than all the arguments that can be adduced, or the laws of analogy or practice of other arts. Reasoning from analogy is feeble when opposed to experience. Gardeners, no doubt, raise crops every year from the same piece of ground; but their practice is not quite analogous to that of the husbandman. They apply a great quantity of manure to their plots, and permit few to remain; they plant to run up the land, the bringing of which to perfection, in the cereal crops, constitutes the great exhaustion to the soil. Gardeners, however, do something like following their ground at stated periods, as every three or four years they dig the ground a double spit of the plane in depth, and lay it up in winter to the frost; and in the subsequent rotations of the alternate pieces of ground, which practices approach nearly to our ideas of summer following." (Quart. Jour. Agr. vol. iii. p. 106.)

499. Fallows unnecessary on friable soils. However necessary the periodical recurrence of follow may be on retentive clays, its warmest advocates do not recommend it on turnips soils, or on any friable loams incumbent on a porous subsoil; nor is it in any case necessary every third year, according to the practice of some districts. On the best cultivated lands it seldom returns oftener than once in six or eight years; and in favourable situations for obtaining an extra supply of manure, it may be advantageously dispensed with for a still longer period. (Sulpit to Euseg. Brit. agr. Agr.)

50. The operation of following, as commonly practised in England, is, in usefulness and effect, very different from what it ought to be. In most places the first furrow is not given till the spring, or even till the month of May or June; or, if it is given earlier, the second is not given till after midsummer, and on the third the wheat is sown. Land may rest under this system of management; but to clean it from weeds, to pulverise it, or to give it the benefits of aeration and heat, is impossible. The farmer, in some cases, purposely delays ploughing his follow, for the sake of the scanty bite the eagle and weeds afford to his sheep; and for the same reason, having ploughed once, he delays the second ploughing. It is not to be wondered at, that under such a system, the theoretical agriculturist should have taken a rooted aversion from what are thus erroneously termed follow. The practice of the best farmers of the northern counties is very different, and that practice we shall here detail.

501. A proper follow invariably commences after harvest; the land intended to be followed getting one ploughing, which ought to be as deep as the soil will admit, even in the best soils; for the cultivation of fallow, as the fresh accession of infertile uncultivated earth becomes afterwards incorporated with the former manured soil, and greatly facilitates the separation of the roots of weeds during the ensuing fallow process, by detaching them completely from the soil, and leaving them to the autumn. This is the method which promotes the rotting of stubble and weeds; and, if not accomplished towards the end of harvest, must be given in the winter months, or as early in the spring as possible. In giving this first ploughing, the old ridges should be gathered up, if practicable, as in that state they are kept dry during the winter months; but they may be so scattered that the plough being not too heavy, or that the portion would be lost, or that the waves may be crooked, that the whole of the crop may be left to the wind, or that the edge of furrow may be left to the weather, which, however seems necessary, that all moisture may have a ready exit. In every place where water is expected to lodge, such as ditches, or hollow places in the field, cross or oblique furrows are drawn by the plough, and their intersections carefully cleared one out by the plow, and their intersections carefully cleared one out by the plow. Wherever possible, it is necessary, cross or oblique furrows are also made cutting the slope, with a pitch, and every possible attention is exercised, that no water may stagnate in any part of the field.

502. As soon as the spring seed-time is over, the fallow land is again ploughed end-long. If formerly split, it is now ridged up; if formerly laid up in gathered ridges, it is split or cloven down. It is then
cross-ploughed; and after lying till sufficiently dry in the admit the harrows, it is harrowed and rolled repeatedly, and every particle of the precarious roofs of weeds brought up to view, carefully gathered by hand into heaps, and either burnt on the field, or carted off to the compost heap. The fallow is then rolled up, which places it in a safe condition in the event of bad weather, and exposes a new surface to the harrows and roller; after which the weeds are again gathered by hand, but a previous harrowing is necessary. It is afterwards harrowed, hurried, rolled, and gathered as often as it may be necessary to reduce it into fine tilth, and completely to eradicate all root weeds. Between these successive operations, repeated crops of seeding weeds are brought into vegetation, and destroyed. The larval' likewise of various insects, together with an infinite variety of the seeds of weeds, are exposed to be devoured by birds, which are then the farmer's best friends, though often proscribed as his bitterest enemies.

4955. The use of the harrow and roller in the fallow process, has been condemned by some writers on husbandry, who allege that frequent ploughing is all that is necessary to destroy root-weeds, by the baking or drying of the clogs in the sun and wind; but experience has demonstrated that frequently turning over the ground, though absolutely necessary while the fallow process is going on, can never eradicate couch-grass or other root-weeds. In all clay soils, the ground turns up to heaps or clogs, which the sooner drought will not penetrate so sufficiently as to kill the included roots. When the land is again ploughed, these heaps are turned over and no more, and the action of the plough serves in no degree to reduce them, as at least very imperceptibly. It may be added, that these heaps likewise ensnare insensible seeds of weeds, which cannot vegetate unless brought under the influence of the sun and air near the surface. The diligent use, therefore, of the harrow and roller, followed by careful hand-picking, is indispensable necessary to the perfection of a fallow process. (General Htsp. of Scotlnd, vol. iv. p. 419.)

4954. The working of fallow by the grubber, is an important modern improvement. We have already described several of these implements, and shall here introduce one which has been made public since the first five hundred pages of this work were printed.

4955. Kirkwood's improved grubber (fig. 723.) has this peculiar advantage, that it removes the whole body of the instrument, and of course all the teeth, can be taken out of the ground at pleasure, and even while the machine is in motion; which is extremely convenient, not only in turning at the head ridges, but whenever an obstruction is met with in the ground, arising from rock, retentive, or other impervious soils. In such of the case would completely intercept the progress of the ordinary instrument, this proceeds with ease, by merely being lifted more or less over them. The operation is performed by the driver bearing with his weight on the guiding handles of the grubber; and this pressure is made to raise the whole machine by a very skilful application of mechanical power. The pressure on the guiding handles (a), it will be observed, turns the whole handle round the axle of the bird-wheel (ac), as round a fulcrum, so that the handle then becomes a lever, on the shorter extremity of which the frame of the teeth rests. It is evident, therefore, that b being on the handle which forms the long end of the lever, the shorter end must be raised, and along with it the harder part of the teeth-frame, and, of course, the teeth also. But there is still another contrivance, by which the force is made to act at the same time on the forepart of the frame, and to raise it likewise. This is done by a long rod (d e), which is attached at the extremity to a fulcrum (d), raised on the handle frame, and at the other in the one end of a bent lever (e f g), which turns on the axle of the fore wheel as a centre, and at an intermediate point carries the fore end of the teeth frame. While the handle, therefore, is depressed, and raises the hinder part of this frame, it is the long lever that, pulling the rod, turns the front lever round the axle of the fore wheel, and so to the means elevates the teeth before as well as behind. The whole operation is simple, ingenious, and efficient. (Highl. Nat. Trans, vol. vii. p. 124.)

4956. When effectually reduced to fine tilth, and thoroughly cleaned from roots and weeds, the fallow is ploughed end-long into gathered ridges or lands, usually fifteen or eighteen feet broad. If the seed is to be drilled, the lands or ridges are made of such widths as may suit the construction of the particular drill machinery to be used. If the seed is to be sown by hand, the lands or ridges are commonly formed into what are called single or double cast ridges; the first of four or more steps, and the latter of eight steps in width. These widths are found the most convenient for a one-handed sower. An expert sower can, however, measure his handful to almost any width; but the above long experience has made the standard. After the land has been once gathered by a deep furrow, proportionate to the depth of the cultivated soil, the manure is laid on, and evenly spread over the surface, whether muck, lime, marl, or compost. A second gathering is now given by the plough; and this being generally the furrow upon which the second ploughing, great care is used to plough equally as possible. After the seed is sown and the land thoroughly harrowed, all the inter-furrows, furrows of the headlands, and oblique or gaw furrows, are carefully opened up by the plough, and cleared out by the spade, as already mentioned, respecting the first or winter ploughing.

4957. The expense of fallowing may appear, from what has been said, to be very considerable, when land has been allowed to become stocked with weeds; but if it be kept under regular management, corn alternating with drilled pulse or green crops, the subsequent returns of fallow will not require near so much labour. In common cases, from four to six ploughings are generally given, with harrowing and rolling between, as may be found necessary; and, as we have already noticed, the cultivator may be employed to diminish this heavy expense. But it must be considered, that upon the manner in which the fallow operations are conducted, depend not only the ensuing wheat crop, but in a great measure all the crops of the rotation. (Supp. to Encyc. Brit. art. Agr. 128.)

Sect. III. General Management of Manures.

4958. The manures of animal, vegetable, or mineral origin have been already described, and their operation explained. (2294.) But a very few of these substances can be obtained by farmers in general; whose standard resources are farm-yard dung and lime, and composts of these with earth. It is on the management of these that we propose to deliver the practice of the best British farmers.
PRACTICE OF AGRICULTURE. Part III.

Section 1. Management of Farm-yard Dung.

4959. The basis of farm-yard dung is straw, to which is added, in its progress through the farm-yard, the excrementitious substances of live stock. From every ton of dry straw, about three tons of farm-yard dung may be obtained, if the after-management be properly conducted; and, as the weight of straw per acre runs from one ton to one and a half, about four tons of dung, on an average of the different crops, may be produced from the straw of every acre under corn. (Husbandry of Scotland, Vol. ii.) Hence it may be noticed the great importance of cutting corn as low as possible; a few inches at the root of the stalk, weighing more than double the same length at the ear.

4960. The conversion of straw into farm-yard dung in the farm-yard, is thus effected:—The straw is served out to cattle and horses. and fed with other hale and fold-yard fodders, either in the proper litter, and commonly for both purposes. Turnips in winter, and green clover in summer, are served to the stock both from the house and yards: on this food the animals pass a great deal of urine, and afford the means of converting the straw into a richer manure than if it were eaten alone. All the dung from the houses, as they are cleaned out, is regularly spread over the yards in which young cattle are left loose, where litter is usually allowed of a great abundance; or over the dunghill itself, if there is one at hand. This renders the quality of the whole mass more uniform; and the horse-dung, which is of a hot nature, promotes the decomposition of the woody fibres of the straw.

4961. The preparation of the contents of the farm-yard for laying on the land, is by turning it over; or, what is preferable, carting it out to a dunghill. The operation of carting out is usually performed during the frits of winter; it is then taken to the field in which it is to be employed, and neatly built in dunghills of a square form, three or four feet each side, and of such a height as circunstances may require.

What is laid up in this manner early in winter, is commonly sufficiently prepared for turnips in June; but if not carried from the straw-yards till spring, it is necessary to turn it once or oftener, for the purpose of separation, and decomposition of the straw yard dung. Thus dung, made in March or April, preparatory to autumn-sown wheat, a much less degree of putrefaction will suffice than for turnips: a clay soil, on which alone fallows should ever be resorted to, not requiring dung so much rotted as a finely pulverised turnip soil; and besides, as the wheat does not need all the benefit of the dung for soundly there is a great deal of broken down matter in the winter, and the nourishment of the plants continued till spring, or later, when its effects are most beneficial.

4962. Management of stable dung. There is a most valuable paper on this subject by Lord Meadowbank. In his ‘還有 the Board of Agriculture concerning the use of farm-yard dung to the Board of Agriculture, that farm-yard dung being the richest manure when completely fermented, it should, if possible, be laid on when very imperfectly, but nevertheless when the process is going on at such a rate that it must continue after mixture with the soil till it is completed. Every gardener knows, that the dung used in hot-houses is to be compared with no other; and even the very fine fresh dung; containing which loss by any accident been kept for years, is of little more value than so much rich earth. Every person of attention, though, must have remarked the great effects which ensue from turning over a dunghill recently built, that compels on it to great power, and the fermentation which the recent mixture of the ingredients has occasioned, and when, consequently, that process is very far from being completed. As farm dunghills are formed by degrees, it is desirable to retain the fermentation of that which is first made, or to retain it in a state of fermentation, so slow of operation, that it may suffer little or nothing after being once made; the finely pulverised, the powerfully fermenting mass; and that then it should be put into the soil, when the process is so far advanced that it will be completed, when, at the same time, little loss of substance has yet been suffered, and when whatever volatile matter is afterwards extricated will diffuse itself through the soil. In these circumstances, every thing is lodged in the soil that the dung can yield, either in point of mass or activity; and at the same time it is in a state when most likely to act as a powerful ferment, for promoting the putrefaction of the decayed vegetables lying inert in the soil. I certainly, therefore, approve of the preserving, from much air, such as would work wind, recognised as an apt to overflow and wash away the manure; but I think the pressure which the feet of animals give, them, especially of the lighter sort, does good, and prevents that violent fermentation which wastes the substance too fast. My opinion, exacting as it is the fertility of the dung, that observance is as good as the time of employing it as a manure calls for it altogether, and at once, into that highly active state of putrefaction, which, though no doubt checked by its distribution in the soil, is sufficient to render the dung effective and complete; and whenever the dung is to be used for composts, it appears to me clearly advantageous to get the dung into the soil as early as possible; it is always wasting somewhat, when kept out of it: but when put into the soil in a proper state, there is the utmost reason to think that what is extricated goes all to fertilise. Give me then, that I do not believe much of this loss is by dissolution, in rain. I am still more, however, to discover the thing of the kind in the water of the furrows of a field properly manured and ploughed. The case, every person knows, is quite different in fields recently limed or dressed with ashes; but I am apt to think, that the volatile and soluble parts of common dunghills have some attraction with the substance of soils, that prevents their escape. We know that common loam extracts the noisome smell of the wooden cloths used for intercropping the earner oils that accompany spirits distilled from the sugar-cane, which scare any deterrent besides can obtain from it; and garden loam, impregnated as it must be with fermenting dung, is certainly not easily deprived of its fertility by the washing of rain. I must also observe, that take one of the great advantages derived from using dung with composts to be, the arresting and preserving the fertilising matter which escapes in the putrefactive fermentation; and another to be, that dung the fermentation, to prevent substances of a nature to separate out, the dung is not rendered ferments, and of its ‘Practice of Agriculture, of husbandmen, is to be careful that his manure industry never be parched and dried up, by which means all the volatile salts would evaporate. He lays his dung, as often as possible, close to his stables and cow-houses, and sheltered from the sun. If this cannot be avoided, he contrives to lay it under large tree, to partake of the shade of its boughs. As a receptacle for their dung, they generally have six feet or seven feet deep, with sufficient space at the top, to receive the dung of March till harvest is over. The more opulent farmers are not satisfied with merely digging such a pit: they further pave and line it with bricks, that the earth should not absorb any of its parts; but that the weights of the weights of a furrow, or six feet further in a row. The stables and cow-houses are paved and sloped in such a manner as to communicate with a drain, which conveys all
the stale of their cattle towards the dung pit, which, by this contrivance, it keeps constantly supplying." (Comm. B. Agr. vol. ii.)

4964. In the application of farm-yard dung to land under tillage, particular attention is paid to the cleanliness of the soil; and to use it at a time when, from the pulverisation of the ground, it may be most intimately mixed with it. The most common time of manuring with farm-yard dung is, therefore, either towards the conclusion of the following operations, or immediately before the sowing of fallow crops. If no dung can be procured but what is made from the produce of the farm, it will seldom be possible to allow more than ten or twelve tons to every acre, when the land is managed under a regular course of white and green crops; and it is thought more advantageous to repeat this dose at short intervals, than to give a larger quantity at once, and at a more distant period in proportion. (General Report of Scotland, vol. ii. p. 517.) Farm-yard dung, it is well known, is greatly reduced in value by being exposed to the atmosphere in small heaps, previously to being spread, and still more after being spread. Its rich juices are exhaled by the sun, or washed away by the rains, and the residuum is comparatively worthless. This is in an especial manner the case with long fresh dung, the far greater part of which consists of wet straw in an entire state. All careful farmers, accordingly, spread and cover in their dung with the plough, as soon as possible after it is brought on the land.

4965. The use of fresh dung is decidedly opposite to the practice of the best farmers of turnip soils; its inutility, or rather injurious effects, from its opening the soil too much, is a matter of experience with every one who cultivates drilled turnips on a large scale. As the whole farm-yard dung, on such land, is applied in May, it results that it has no action in its mass, and that none of its effects are observable from it, till the fall of the year, when it begins to ferment. It may be said, therefore, that a much larger proportion of dung, and of that which is essential to the fertility of the soil, is prudently given to the land, by farmers who have not the turnip to carry off the dung, and those that use it, than is, or ever was, the case with the farmer who can grow turnips, and turnip crops of the best quality, as a thorough manurial manure. Another great objection to the use of fresh farm-yard dung is, that the seeds and roots of those plants with which it commonly abounds spring up luxuriantly on the land; and this evil nothing but a considerable degree of fermentation can obviate. The mass of materials consists of the straw of various sorts, some of the grains of which, after all the care that can be taken, will adhere to the straw; of the dung of different animals voided, as is often the case with horses fed on oats, with the grain in an entire state, the droppings of birds, stems, and seeds of the weeds that had grown among the straw, clover, and hay, and such as had been brought to the houses and fold-yards with the turnips and other roots given to live stock.

4966. The degree of decomposition to which farm-yard dung should arrive, before it can be deemed a prudential manure, must depend on the texture of the soil, the nature of the plants, and the time of its application. In general, clayey soils, as more tenacious of moisture, and more benefited by being rendered cohesive and porous, may receive manure less decomposed than well pulverised turnip soils require. Some plants, too, seem to thrive better with fresh dung than others, potatoes in particular; but all the small-seeded plants, such as turnips, clover, carrots, &c. which are extremely tender in the early stage of their growth, require to be pushed forward into luxuriant vegetation with the least possible delay, by means of short dung.

4967. The season when manure is applied, is also a material circumstance. In spring and summer, whether used for corn or green crops, the object is to produce an immediate effect, and it should therefore be more completely decomposed than may be necessary when laid on in autumn for a crop whose condition will be almost stationary for many months. (Sup. Ency. Brit. art. Agr.)

4968. The quantity of putrescent manure requisite for each acre of land during each year is estimated, by Professor Coventry, at five tons per acre annually. That quantity being supplied, not annually, but in quantities of twenty tons per acre every four years, or twenty-five tons per acre every five years. (Quar. Jour. Agr. vol. ii. p. 335.)

\textbf{Subject. 2. Lime, and its Management as a Manure.}

4970. Lime is by far the most important of the fossil manures; and, indeed, it may be asserted, that no soil will ever be fit for much which does not contain a proportion of this earth, either naturally or by artificial application. Next to farm-yard dung, lime is in most general use as a manure, though it is one of a quite different character; and when judiciously applied, and the land laid to pasture, or cultivated for white and green crops alternately, with an adequate allowance of putrescent manure, its effects are much more lasting, and, in many instances, still more beneficial, than those of farm-yard dung. Fossil manures, Sir H. Davy observes, must produce their effect, either by becoming a constituent part of the plant, or by acting upon its more essential food, so as to render it more fitted for the purposes of vegetable life. It is, perhaps, in the former of these...
ways that wheat and some other plants are brought to perfection, after lime has been applied, upon land that would not bring them to maturity by the most liberal use of dung alone. This being an established fact may be considered one of the greatest importance to all cultivators.

With regard to the quantity of lime that ought to be applied to different soils, it is much to be regretted that Sir Humphry Davy has not thought proper to enter fully into the subject. Clays, it is well known, require a larger quantity than sands or dry loams. It has been applied accordingly in almost every quantity from 100 to 500 bushels or upwards per acre. About 160 bushels are generally considered a full dressing for lighter soils, and 80 or 100 bushels more for heavy cohesive soils. One of the greatest advantages arising from the use of lime on gravelly or sandy soils, is its power of absorbing moisture from the air, which is in the highest degree useful to the crops in dry summers.

In the application of lime to arable land, there are some general rules commonly attended to by diligent farmers, which we shall give nearly in the words of a recent publication.

1. As the effects of lime greatly depend on its intimate admixture with the surface soil, it is essential to have it in a powdery state at the time it is applied.
2. Lime having a tendency to sink in the soil, it should be ploughed in with a shallow furrow.
3. Lime may either be applied to grass land, or to land in preparation for green crops or summer fallow, with almost equal advantage; but, in general, the latter mode of application is to be preferred.
4. Lime should not be applied a second time to moory soils, unless mixed up as a compost, after which the land should be immediately laid down to grass.
5. Upon fresh land, the effect of lime is much superior to that of dung. The ground, like wise, more especially when the quality of the soil is of a strong nature, is more easily wrought; in the bulk of it, is said, the savour of labour would be sufficient to induce a farmer to lime his land, were no greater benefit derived from the application than the opportunity thereby gained of working it in a more perfect manner. (General Report of Scotland, vol. ii. p. 535.)

In liming for improving hilly land, with a view to pasture, a much smaller quantity has been found to produce permanent and highly beneficial effects, when kept as much as possible near the surface, by being merely harrowed in with the seeds, after a fallow or green crop, instead of being buried by the plough.

The successful practice of one of the most eminent farmers in Britain cannot be too generally known to a matter of so great importance to farmers of such lands, as to be brought from a great distance, as was the case in the instance to which we are about to allude. "A few years after 1784," says Dawson, "having a considerable extent of outfield land in fallow, which I wished to lime previously to being laid down to pasture, and finding that I could not obtain a sufficient quantity of lime for the whole, I was induced to try observing no other mixture of lime and soil, even when covered with bent, to try a small quantity of lime on the surface of this fallow, instead of a larger quantity of lime as it has, in the usual manner. Accordingly, in the autumn, about twenty acres were well harrowed, and then about fifty, the same after being harrowed, carefully spread upon each English acre, and immediately well harrowed in. As many pieces of the lime, which had not been fully sacked at first, were gradually reduced to powder by the dews and moisture of the earth, to mix these with the soil, the land was again well harrowed in three or four weeks. This land was brought upon the same system as the one on the other side, during the spring; yet with the same results, the crops of grass and of wheat were abundant, and so rising and renewed, and sowed oats and grass seeds in the spring exactly as in the last-mentioned experiment. The oats were a full crop, and the plants of grass abundant. Several of these fields have been now above thirty years in pasture, and are still producing white clover, and other fine grasses; no bent or bog has yet appeared upon them. It deserves particular notice, that more than twice the quantity of lime was laid upon fields adjoining, of a similar soil, but which being firmer for occasional tillage, upon them the lime was ploughed in. These fields were also sown with oats and grass seeds. The latter throw well, and gave a fine pasture the first year; but afterwards the bent spread so fast, that in three years, this was more of it than of the best grasses."
natural poverty; that the objection made to this, viz. that the coarse grasses in a few years usurp possession of the soil, must be owing to the surface soil not being sufficiently mixed with lime, the lime having been covered too deep by the plough. (Farmer's Magazine, vol. xii. p. 93.)

**SECT. IV. Composts and other Manures.**

4976. Mixing farm-yard dung, in a state of fermentation, with earth, in which there is much inert vegetable matter,—as the banks of old ditches, or what is collected from the sides of lanes, &c.,—will bring this inert, dead matter, consisting of the roots of decayed grasses and other plants, into a state of putridity and solubility, and prepare it for nourishing the crops or plants it may be applied to, in the very manner it acts on peat. Dung, however, mixed with earth, taken from rich arable fields which have been long cultivated and manured, can have no effect as manure to other land that the same earth and dung would not produce applied separately; because there is generally no inert matter in this description of earth to be rendered soluble.

4977. Mixing dung, earth, and quick-lime together, can never be advisable; because quick-lime will render some of the most valuable parts of the dung insoluble. (See 2290.) It will depend on the nature of soil or earth, whether even quick-lime only should be mixed with it to form compost. If there be much inert vegetable matter in the earth, the quick-lime will prepare it for becoming food for the plants it may be applied to; but if rich earth be taken from arable fields, the bottoms of dung-pits, or, in fact, if any soil full of soluble matter be used, the quick-lime will decompose parts of this soluble matter, combine with other parts, and render the whole mass less nourishing as manure to plants or crops than before the quick lime was applied to it. Making composts, then, of rich soil of this description, with dung or lime, mixed or separate, is evidently, to say no more of it, a waste of time and labour. The mixture of earths of this description with dung produces no alteration in the component parts of the earth, where there is no inert vegetable substances to be acted on; and the mixture of earth full of soluble matter with dung and quick-lime, in a mass together, has the worst effects, the quick-lime decomposing and uniting with the soluble matter of the earth, as well as that of the dung; thus rendering both, in every case, less efficient as manures, than if applied separately from the quick-lime, and even the quick-lime itself inferior as manure for certain soils, than if it had never been mixed with the dung and earth at all. (Farmer's Magazine, vol. xv. p. 351.)

4978. Mixing dung in a state of fermentation with peat, or forming what in Scotland are called Meadowbank middens (2241.), is a successful mode of increasing the quantity of potaceous manure. The peat, being dug and partially dried, may either be carted into the farm-yard and spread over the cattle court, there to remain till the whole is carted out and laid upon a dunghill to ferment; or it may be mixed up with the farm-yard dung as carted out. If care be taken to watch the fermenting process, as the fire of a clay-kiln is watched, a few loads of dung may be made to rot many loads of peat. Adding lime to such composts does not in the least promote fermentation, while it renders the most valuable parts of the mass insoluble. Adding sand, ashes, or earth, will, by tending to consolidate the mass, considerably impede the progress of fermentation.

4979. Bone manure. Crushed bones were first introduced to Lincolnshire and Yorkshire, about 1800, by a bone merchant at Hull; and the effect has been, according to a writer in the British Farmer's Magazine, vol. iii. p. 207., to raise wild unclosed sheep-walks from 2s. 6d. or 5s. to 10s. 6d. or 20s. an acre. The quantity at present laid out is 12 bushels per acre drilled in, in the form of dust, with turnip seed. The turnips are fed off with sheep, and succeeded by a corn crop, and by two crops of grass. It seems to be generally admitted, that bone dust is not beneficial on wet retentive soils, as continued moisture prevents decomposition; but in all descriptions of dry soils it never fails of success. On the poor soil, or chalk or lime-stone of the woods of Lincolnshire and Yorkshire, the turnip crops are said to equal those of any part of England; and the barley, though coarse, to produce a greater quantity of saccharine matter than even the brightest Norfolk samples. (Brit. Farm. Mag. vol. iii. p. 208.)

4980. The Doncaster Agricultural Association appointed a committee, in 1833, to make enquiries, and report the result of them, on the use and advantages of bones as a manure. The report is full of interest, and highly satisfactory as to the great value of this species. The following is a summary of deductions from the details collected:

1. That on dry sands, lime-stone, chalk, light loams, and peat, bones form a very highly valuable manure; they may be laid on grass with great good effect; and, on arable lands, they may be laid on fallow for turnips, or used for any of the subsequent crops.
2. That the best method of using them, when broad-cast, is previously to mix them up with earth, dung, or other manures, and let them lie to ferment.
3. That if used alone, they may either be drilled with the seed or sown broad-cast.
4. That bones which have undergone the process of fermentation are decidedly superior to those which have not done so.
5. That the quantity should be about 25 bushels of dust, or 40 bushels of large, increasing the quantity if the land be impoverished.
6. That upon clays and heavy loams, it does not yet appear that bones will answer.
4981. Salt, nitre, and other manures have been already treated of in Part II. at sufficient length. It is clear that both salt and nitre may be advantageously used in many cases. Nitre continues to be a good deal used in Hertfordshire, on which it is sown at the rate of 1½ cwt. per acre. It has been tried at this rate in Scotland to wheat and to grass, and the effect is said to have been wonderful. Salt has been extensively used with almost every crop at different rates, from 20 to 40 bushels per acre; and it appears in many, if not in most, cases to have proved useful. (Quar. Jour. Agr. vol. i. p. 208., and Highl. Soc. Trans. vol. i. p. 147.)

CHAP. II.

Culture of the Cereal Grasses.

*4982. The corn crops cultivated in Britain are, wheat, rye, barley, and oats. Other culmiferous plants, as the maize, millet, and rice, have been tried with partial success in warm districts, but they have no chance of ever becoming general in our climate. The best description of the different species and varieties of Cerealia cultivated in Europe will be found in Metzger's Europäische Cerealien in Botanischer und Landwirtschaftlicher Hinsicht, &c. Heidelberg, 1824. Folio, 20 plates. The plates are exceedingly well executed; and there are popular as well as scientific descriptions, with synonyms in all the European languages.

4983. On the culture of culmiferous plants, a few general remarks may be of use to the young farmer. Culmiferous plants, particularly wheat and rye, like most others, have two sets of roots. The first originate with the germination of the grain, are always under the soil, and are called the seminal roots; the second spring from the first joint which is formed near the surface of the soil, and from that joint strike down into the soil; these are called the coronal roots. The coronal roots appear chiefly intended for drawing nourishment from the soil; and, as Professor Martyn has observed, are judiciously placed for this purpose, the richest part of all soils being on or near the surface. These fibres are of larger diameter, more succulent, and never so long as the seminal. From these facts, as to the roots of culmiferous plants, some important hints may be derived regarding their culture. The use of stirring the surface in spring to facilitate the extension of the coronal roots, is obvious; the immediate effect of a top-dressing is also apparent, and also that manures may be ploughed in too deep to give the full amount of their beneficial effects to corn crops or grasses. Sageret, a scientific French agriculturist, proved experimentally, that where any of the grains or grasses are etiolated immediately after germination, by growing too rapidly, or by being sown too thick or in too warm a season, the first joint from which the coronal or nourishing roots spring is raised above the ground, and in consequence either throws out no roots at all, or so few as to nourish it imperfectly; in which case it either dies before it comes into flower, or before the seed is matured. (Mem. de la Soc. Agr. de Scine, tom. ii.)

4984. Whether corn ought to be sown broadcast or in drills, is a question which has given rise to considerable discussion. The cultivation in rows of such plants as admit of tillage during the summer months, is known to supersede the use of a summer fallow on lighter soils. "In truth, the row culture of certain green crops is one of the greatest improvements of modern agriculture, and should be extended by every effort of instruction and example. By no other means yet known to us can so large a produce be raised from land under constant tillage, so beneficial a rotation of crops be adopted, or so great an economy be practised in the application of manures. But, while the advantages are thus apparent with regard to the application of this species of culture to our preparatory green crops, it does in no degree follow that advantages equally great will result from its application to our crops of white corn. The analogy, as it regards the nature of the plants which form the subject of cultivation, does not hold. The cereal grains send forth numerous shoots or suckers, and the goodness of the crop mainly depends on the vigour and number of the shoots which they send forth. The other kind of crops do not, generally speaking, tiller like wheat, barley, or oats, but rise from one stem. Reasoning from these principles, we should infer that the former class of plants should be cultivated in that manner in which they are best suited to summer tillage; that is, in rows; the latter in that manner in which the seed is most equally deposited in the upper stratum of the soil, which is in broadcast. The opinions, however, of intelligent agriculturists are not agreed as to the superiority in practice of the broadcast over the row system, even as it relates to the cereal grains. The farmer of Norfolk, or of the light soils of Sussex, will contend as strenuously for the superiority of the row system as the farmer of East Lothian for the broadcast system; and each may be right as it regards the application of the principle to the circumstances of his own situation. The question which is to be settled, however, is,—Which of the two systems
is to be regarded as the rule in husbandry, and which the exception? Now,—independently of the circumstances just adverted to, and judging only from the greater extent to which the broad-cast system is carried on in the country; from the fact of the row system having declined in favour in districts where it had once been most extensively practised; and from its having recently ceased to make progress in general practice,—we should be inclined to hold that, with respect to the cereal grains, the rule of agriculture is the broad-cast system, and the exception the row system. The cases falling under the exception may be, and doubtless are, very numerous and important. There are many light soils in which the seeds require to be deposited at a considerable and equal depth, and this the drill-machine effects better than sowing on the surface; and there are many thin cold clays which tend to throw out the plants, the best remedy for which is thought to be deep sowing."

4985. The sowing of corn from the hand, "however, is known to be attended with some uncertainty; being dependent for the accuracy of the execution upon the skill and attention of the sowers. The regularity of the work is also affected by winds; and, unfortunately, the means rarely exist of detecting the degree of inaccuracy in the work until too late to correct it." As a remedy for these inconveniences, we have already described a broad-cast hand drill (2576.), and shall here introduce a horse machine for the same purpose (fig. 722 a, b), that has been for some years employed in "the agriculture of Northumberland, North Durham, and some of the southern counties of Scotland, for sowing broad-cast. As it regards economy alone, little perhaps is effected by the employment of this machine; its recommendations are the regularity and certainty with which it performs the work, and the rendering of the execution independent of unskilfulness or want of care in the operator." (Quar. Jour. Agr. vol. ii. p. 256.)

4986. The preservation of corn after it is threshed and cleaned is generally effected in granaries, where the grain is kept well ventilated by passing it frequently from one floor to another, or through winnowing machines.

4987. It has been proposed and attempted in France to preserve it in pits or dry cells at an equal temperature, and included from the atmosphere; but the experiments now going on for this purpose, more
especially by M. Ternaux at St. Ouen, near Paris, are not yet sufficiently matured to enable us to lay any useful result before the public. That corn has been so preserved in former ages, and that to a considerable extent, is beyond a doubt; and it is equally certain that in the interior of Africa, among the Cafrises and other African tribes, and in Ethiopia, the same process, in the same manner, has been carried on a small scale. It may be doubted, we think, whether, with the present population of Europe, it could ever be generally adopted.

4888. Preservation of corn in silos. Some account of the opening of a silo was lately read to the Agricultural Society of Paris. The place consisted of an icehouse, and the grain when put in was of the finest appearance, perfectly dried, and in excellent condition. The door had been hermetically sealed; and, when opened, a considerable thickness of the mass of corn was found destroyed by weevils, the latter being in such quantity as to deprive the silo of as much corn as had been perfectly well preserved in other silos, the cause of this deterioration was sought for, and a hole was found in the lower part which had been made by mice, and which, by admitting air in sufficient quantity, had allowed the weevils originally in the corn to live. The mice, and indeed all their numbers, to the degree mentioned. After such observations as thus showed that insects could live for a very long time in a stated air, a committee was named to ascertain the requisite state of the air, and the circumstances connected with the preservation of grain in these repositories. At another meeting of the society, balances were produced by M. Lefebre proving the general propagation of weevils. It is founded upon a fact observed by him, that these insects cannot live in an atmosphere which contains less than a certain proportion of moisture. He therefore proposes that the corn should be subject to a continued ventilation of air dried by passing over quicklime or chloride of calcium. All the weevils originally in the corn would thus be quickly destroyed.

(Recueil Industriel, vol. xii. p. 208.)

4889. The preservation of corn in the north of Russia may deserve notice more as matter of curiosity, and for supplying ideas on the subject, than for imitation. The corn is dried in small ovens or chambers, which communicate with a larger chamber or oven by small tubes that enter the smaller chambers at the top. The oven is then filled with straw closely pressed, which is lighted and left to consume during the night. Next morning the corn is taken from the smaller chambers, the smoke from the ovens having passed into them and thus perfectly dried; the air is then expelled from this practice. The same practice is used as before, but kept much easier, without requiring to be constantly turned, being preserved from vermin by the smoky taste communicated to it by the straw, which does not quit it until it has passed through the mill. The corn intended to be kept for any length of time is put into pits, in shape like a bottle, sufficiently high for the air, which is injected there, to ascend in it, which are dug in elevated places. When they are dug a fire is lighted for four and twenty hours, which forms a hard crust round the pit. The interior is lined with the bark of the birch tree, fastened with wooden nails. Some straw is then put at the bottom, upon which the corn is placed; and, before the pit begins to smoulder, the top, the mouth, and all the rest is filled with straw in the form of a cone. Each pit contains from twenty-five to one hundred bushels, and the grain in them will keep for twenty years without being injured. (Bibliotheque de Geow.)

4900. The uses to which the straw of corn may be applied are various. Besides food for cattle, litter for animals, thatch, &c., it is bleached and plated into ribands for forming hats, and bleached, dyed of different colours, split, and glued to flat surfaces, so as to form various works useful and ornamental. Paper is also made from straw; and the same pulp which forms the paper may be moulded into all the forms given to papier maché, medallion portraits, embossed works, &c. Whoever wishes to enter into the details of the great variety of articles that may be manufactured from straw, should consult the Dictionnaire Technologique, art. Paille; or an abridgment translated of a part of the article in Gill’s Technological Repository, vol. vi. new series, p. 228.

*4901. The diseases peculiar to the cereal grasses have been included in the diseases common to vegetables in general. (1671.) They are chiefly the smut, the rust, the mildew, and the ergot; and we shall notice them more at length under the different species of corn which are most subject to suffer from them.

*4902. The practice of reaping corn before it is perfectly ripe originated in France, and has lately been recommended by M. Cadet de Vaux.

4903. Corn reaped eight days before the usual time, this author says, has the grain fuller, larger, finer, and better calculated to resist the attacks of the weevil. An equal quantity of the corn thus reaped, with corn reaped at the period of maturity, gave more bread, and of a better quality. The proper time for reaping is that when the grain, on being pressed between the fingers, has a doughy appearance like the crumb of bread just hot from the oven, when pressed in the same manner. This does not seem to agree altogether with the experience of some agriculturists in the Carse of Gowrie, Perthshire, where oats intended to be made into meal are always found to yield most when allowed to stand as long as possible. Corn for seed, however, it is acknowledged by the same agriculturists, will answer the purpose perfectly though cut before fully matured. (Perth Miscellany, vol. i. p. 41.) If the doctrine of Cadet de Vaux be confined to wheat, it may perhaps be considered as confirmed by the following passage from Wallstell:—

"It is well observed, that wheat produces the most flour and the best bread when threshed out before it has been stacked; and as all corn is more or less injured in both these respects, accordingly as it is more or less heated in the stack, it would be highly desirable totally to prevent its heating or cooling. In the rarest instances it is sometimes spoiled in the ricks; and we see that even in hot and dry harvests, such as that of 1819, a great deal of corn is sometimes spoiled in the ricks: we should, therefore, be extremely cautious to have corn well dried in the field, the ricks made of a moderate size, and raised off the ground, to admit the air to circulate under them, with chimneys to allow a current of air through them, to carry off the hot and musty air from the centre of the rick, which, without such a chimney, has its tendency to heat four-fold greater than one with a chimney. Chimneys being easily made, and so beneficia, it were to be wished that they were in general practice. (Miscellany, of rural Buildings, p. 10.)"

4904. For seed corn, it not only appears that unripe grain is preferable, but even that middled wheat and oats answer perfectly. Mr. S. Taylor, the editor of the Country Times, and formerly an extensive large-seed grower, takes it from 100 to 130 bushels of wheat annually for 30 years and upwards. "The seed was invariably chosen, not from the best and largest, but from the thickest, but the thickest, but the middle mildewed seed." He has seen the most beautiful samples of wheat produced from seed of the most ordinary description. (Country Times, March 22, 1830.) In Perthshire, the same is stated with respect to oats. (Perth Miscellany, vol. i. p. 41.)

*4905. The methods of reaping corn are various. The most general mode is by the sickle, already described (2482. and 2483.); the scythe is also used, more especially for barley and oats; and a reaping machine (2787.) is beginning to be used in some parts of Scotland; in which country an effectual bean-reaping machine (2787.) was
in use many years ago. A method of mowing corn much practised in the county of Durham, and possibly Yorkshire, has lately been introduced into Northumberland, but does not appear to make much progress, the low priced Irish reapers doing the work so much more neatly and with less waste, though it costs more money to the owner. The scythe has a blade similar to that described (405.); it is handled and used differently from the bow and grass scythes, and has only one short handle or "nib" on the "sled," or long handle, for the right hand; the left grasps the "sled" with the palm upwards: this enables the mower, who generally mows "from the corn," to bring the back of the scythe and cradle to the ground, and leave the cut corn in a beautiful state for being put into sheaves. A good workman can do two, and some three acres a day: they charge about 5s. per acre for mowing, binding, and stooking (shocking): this practice may be advantageously followed whenever the crop is not stricken down by rains, particularly barley crops. (C. near Alnwick, in Gard. Mag. vol. vi.)

4996. Frosted corn, like frosted seeds of any sort, may be detected by dissection and comparison with unfrosted corn. By frosted corn is to be understood corn that has been frozen on the plant before it was perfectly ripe, in consequence of which the germ of the future plant or vital part of the seed is deprived of its vitality by the expansion produced by the freezing of its watery parts.

4997. Frosted oats. The oat being one of the latest corns, and a corn of cold rather than of warm countries, is more liable to be frozen than any other; but fortunately, also, frozen oats are more easily detected than either of the others. Rev. James Farquharson, who has paid much attention to this subject, and written an elaborate article on it in the Farmer's Magazine (vol. xiv.), observes, that every kernel, when stripped of the husk, will be found to exhibit the appearance of a groove on one side. If the bottom of the groove has a smooth clear translucent appearance from end to end; if it is not much shrunk into the substance of the kernel; and if the kernel splits with difficulty in its direction, then we may pronounce the vital part of the seed to be free from injury by frost. If, on the contrary, there is a black speck seen in the groove at the root end of the kernel; if the groove cuts deep into the kernel, so that it may be split in that direction; or if, when the seed is split, it may be seen the blackness, accompanied with a rotten scaly appearance, is seen extending from end to end at the bottom of the groove, then the vital part or future plant may be pronounced entirely unfit for being used as seed.

4998. Frosted barley. The nature of the injury that ripening barley suffers from frost is similar to that suffered by oats. The husk of barley, like that of oats, consists of two unequal parts; the small part covering the groove of the kernel. In sound grain, when dry, the hull is firmly attached to the kernel; but in frozen grain the small part of the hull becomes loose, and feels soft on being pressed; and if, in such grain, this part of the hull is stripped away, a blackness and rottenness, resembling that in frosted oats, will be seen in the bottom of the groove. In frosted barley the husk becomes loose all round the root end; but, this is a circumstance that is occasionally observed likewise in barley that was never exposed to frost; it certainly sometimes arises from other causes,—perhaps from wet; and this, unless the grain has germinated, does not render it unfit for seed or malting. The only sure mark of damage from frost is the blackness and rottenness in the bottom of the groove.

4999. Frosted wheat. Upon an attentive inspection of wheat that has been exposed to the frost, it will be observed that in a large proportion of grains there is a rotten scaly appearance where the embryo of the plant is attached to the coryleoid or mealy part of the grain; that the groove is much deeper than in wheat that was saved before the frost; and that the grains are easily split in its direction. From this it is inferred that wheat, in its ripening stage, suffers from frost an injury of the same nature with that sustained by oats and barley. (Farm. Mag., vol. xix.)

5000. The nutritive products of the plants to be treated of in this section, are thus given by Sir H. Davy.

5001. Wheat is by far the most important of the cereal grasses, the flour made from its grains or seeds, from the quantity of gluten they contain, making the best bread in the world. A greater proportion of mankind are nourished by rice than by wheat, but there is no grain which comes near wheat in its qualities for bread-making. Rice and maize are comparatively unfit for it, and oats, barley, and rye but imperfectly adapted. Rye, however, comes nearer to wheat in its bread-making qualities than any other grain.

5002. Of what country wheat is a native, is totally unknown; it has been supposed indigenous to Asia and Africa, and unquestionably it is more likely to belong to these
parts of the world than any other; but all that can be advanced on this subject is conjecture. Wheat, with the exception it is said of some parts of the southern coast of Africa, is cultivated in every part of the temperate and torrid zones, and in some places as high as 2000 feet above the level of the sea. It has been grown from time immemorial in Britain, but in few places at a greater elevation than 600 feet. Of course the elevation to which any plant can be cultivated always depends on the latitude of the situation.

5003. Species and varieties. (fig. 723.) Botanists reckon seven species of Triticum, which are or may be cultivated for their grains, besides many varieties and subspecies of those in common culture. The species or subspecies are,

5. *Triticum paleocoeum*, Polish wheat (e).
7. *Hordeum*, One-grained wheat (g).

The first, second, fourth, and fifth sorts are by many botanists considered as only varieties, and it is doubtful whether the third and sixth may not be the same; the seventh has all the marks of a distinct species, but it is very questionable whether, if much cultivated, it would always continue to produce one row of grains.

5004. The spring or summer wheat (a), *Elo de Mars*, Fr., is distinguished from that generally sown, by its narrower ears, longer beards, smaller grains, and shorter and more slender straw, and also by its inability to endure our winters. It is commonly sown in April, or even so late as May. It was known to Parkinson in 1660, but has never been much cultivated, except in Lincolnshire. It was tried and given up in Northumberland and Mid Lothian, and also in some counties near London. Many varieties of summer wheat were transmitted a few years ago to the president of the Board of Agriculture from the Agricultural Society of France, for the purpose of experiment, and were divided among several distinguished agriculturists, (Comm. to the Board of Agr., vol. vii, p. 11.); but there has not yet been time for establishing their comparative merits, or their adaptation to the climate of Britain. Summer, or, as it is often called, spring wheat has however been long and extensively cultivated in some parts of England, particularly in Lincolnshire; and it is probable may be found a valuable crop in the southern counties; but the trials that have been made in the north, do not seem to entitle it to a preference over winter wheat sown in spring, or even oats or barley, in that climate.

5005. Of the winter or common wheat (b), *Froment blanc*, Fr., there are a great number of varieties. Professor Martyn, in Miller's Dictionary, has described forty-nine sorts, and Professor Thacker speaks of a hundred, but affirms that those who describe them know nothing about them, and in all probability include one sort under different names. All the varieties may be reduced to two, the white, and the brown or red grained. As varieties, there are the bearded and beardless, the woolly-chaffed, and thin or hairy chaffed, both of the reds and whites. To these some add another variety, which is the spring-sowing common wheat. It is stated by those who maintain that this variety exists, that through long sowing the progeny, after a number of generations, acquires a habit of coming earlier into blossom than seed from winter-sown grain. This we think very likely, but are not aware that the variety is distinctly known by any recognizable marks of the plant. The red and brown wheats are universally considered more hardy than the white, but as yielding an inferior flour: the woolly-white is supposed to yield the best flour; but woolly-chaffed wheats are considered more liable to the mildew than any other.

5006. The Egyptian, or many-spiked wheat (c), *Elo de miracle ou de Smyrne*, Fr., the turgid grey polled or duck-tail wheat (d), and the Polish wheat (e), may, for all agricultural purposes, be considered only varieties of the common winter wheat. They are cultivated in a few places in England, and seeds of them may be procured from the public botanic gardens; but they are in little estimation.

5007. *Spelt wheat* (f), the *Espérance* of the French, is known by its stout straw, which is almost solid, and by its strong pikes, with chaff partially awned, the awns long and stilt. The chaff adheres so closely to the grain as not to be separated without great difficulty. This grain, as we have seen, is a good deal sown in the south of Europe. In France it is sown in spring, on land too coarse for common wheat, and it ripens in July and August. It is the principal wheat sown in Sardinia and the north of Switzerland; and is a good deal sown in Spain. The grain is light, and yields but little flour; but it is said to contain a larger portion of gluten than common wheat, and for that reason is recommended as superior to any other in particular confectionary. It is not cultivated in Britain.

5008. The one-grained wheat (g), *Petit épanette*, Fr., is known by its small thin spike, and single row of grains; the leaves and straw are remarkably small, but very hard; and the plants taller very much. It is chiefly cultivated in the mountainous parts of Switzerland, where its straw, like that of the former species, is much used for thatching. The grain makes a brown light bread; but its great excellence, according to Villars, is for gruel.
5009. *To procure new varieties of wheats,* the ordinary mode is to select from a field a spike or spikes from the same stalk, which has the qualities sought for; such as larger grains, thicker chaff, stiffer straw, a tendency to earliness or lateness, &c.; and picking out the best grains from this ear or ears, to sow them in suitable soil in an open airy part of a garden. When the produce is ripe, select the best ears, and from these the best grains, and sow these, and so on till a bushel or more is obtained, which may then be sown in a field apart from any other wheat. In this way, many of the varieties of our common winter wheat have been obtained; as the hedge-wheat which was reared from the produce of a stalk found growing in a hedge in Sussex, by one Wood, about 1790. Other varieties have assumed their distinctive marks from having been long cultivated on the same soil and climate, and take local names, as the Hertfordshire red, Essex white, &c.

5010. Marshall, (Yorkshire) mentions a case in which a man of accurate observation, having in a piece of wheat possessed a plant of uncommon strength and luxuriance, diffusing its branches on every side, and setting its closely-surrounding neighbours at defiance, marked it; and at harvest removed it separately. The produce was 15 ears, yielding 604 grains of a strong-bodied liver-coloured wheat, differing, in general appearance, from every other variety he had seen. The chaff was smooth, without awns, and of the colour of the grain; the straw stout and reedy. These 604 grains were planted singly, nine inches asunder, tilling about 40 square yards of ground, on a clover stubble, the remainder of the ground being sown with wheat in the ordinary way; by which means extraordinary trouble and destruction by birds were avoided. The produce was two gallons and a half, weighing 50lbs. of prime grain for seed, besides some pounds for seconds. One grain produced 15 ears, yielding 1555 grains; so that the second year's produce was sufficient to plant an acre of ground. What deters farmers from improvements of this nature is probably the loss of 3-4 bushels and a quarter per acre, which, when comparing a patch of corn, especially in a garden or other ground situated near a habitation; but by carrying on the improvement in a field of corn of the same nature, that inconvenience is got rid of. In this situation, however, the botanist will be apprehensive of danger from the diminution of the faunas of the surrounding soil, unless the worst is not made he is of opinion his fears will be groundless. No evil of this kind occurred, though the cultivation of the above variety was carried on among white wheat.

5011. *But the most systematic mode of procuring new varieties,* is by crossing two sorts, as in breeding; thus if a flower bearing the blossoms of one sort, and the pollen of the male organs of the blossom of another variety of a different quality. Thus, supposing a farmer was in the habit of cultivating a very good variety, which he wished to render somewhat earlier, impregnate it with an early sort; or with an early, smooth, liver-coloured, and let him sow the seeds of these in water, and set them in the shade so as to retard their fully blossoming till the plants he has destined to become the females come into flower. Then let him cut out all the male organs of the latter, before they have advanced so far as to impregnate the stigmas; and, having delayed them till he has the blossoms of some of the earlier, smooth, liver-coloured sorts, he may then cross till the plants have been impregnated. The impregnated plants must then be kept apart from other wheats that the progeny may be true. When the grains ripen, let him sow the best; and from the produce, when ripe, select the earliest and finest spikes for seed. Let him sow these, and repeat the process till he produces a choice till or ground. To the best plant he has made, A. Knight (1635); and though it may be reckoned too delicate for farmers in general, it will be looked on by the philosophical agriculturist as not improbably leading to results as important as those which have attended this practice in the case of garden fruits and flowers. The scientific farmer may consult on this subject Bishop's *Causal Botany* already referred to, to the *Gardener's Magazine,* and *Saggio Botanico Georgico intorno l'ibridismo delle Piante,* by Billardi. *Pavia, 1856.*

5012. The propagation of wheat by transplanting may be employed to expedites the progress of cultivating a new variety of ascertained excellence. To show what may be gained in time by this mode, we shall quote from *The Philosophical Transactions* an account of an experiment made by C. Miller, son of the celebrated gardener of that name, in 1798. On the 9th of June,Miller sowed some grains of the common red wheat of England, which was taken out of a fertile plant, and planted separately. These plants having pushed out several side shoots, by about the middle of September, some of them were then taken up and divided, and the rest of them between that time and the middle of October. This second division produced 67 plants produced by the first division, and there was a third division the middle of March and the 15th of April, produced 500 plants. They were then divided no further, but permitted to remain. The plants were, in general, stronger than any of the wheat in the fields. Some of them produced upwards of 100 ears from a single root. Many of the ears measured seven inches in length, and contained between 60 and 70 grains. The whole number of ears which, by the process above mentioned, were produced from one grain of wheat, was 21,169, which yielded three pecks and three quarters of clean corn, the weight of which was 47lbs. 7 ounces; and, from a calculation made by counting the number of grains in an ounce, the whole number of grains was about 386,546. By this account we find, that there was only one general division of the plants made in the spring. Had a second season, Miller thinks the number of plants would have amounted to 2000 instead of 500, and the produce thereby much enlarged.

*5013. In making a choice from all the species and varieties which we have named, the thin-skinned white wheats are preferred by all the best British farmers whose soil and climate are suitable for this grain, and for sowing in autumn. In late situations, and less favourable soils and climates, the red varieties are generally made choice of; and these are also generally preferred for sowing in spring. Red wheats, however, are considered as at least fifteen per cent, less valuable than the white varieties. No subvariety ever continues very long in vogue; nor is it fitting that it should, as degeneracy soon takes place, and another and better is sought for as a successor. Hence the only recommendation we can give, as to the choice of subvarieties, is, to select the best from among those in use by the best farmers in the given situation, or nearest well-cultivated district.*

5014. The *soils best adapted for the culture of wheat,* are rich clays and heavy loams; but these are not by any means the only description of soils on which it is cultivated. Before the introduction of turnips and clover, all soils but little cohesive were thought unfit for wheat; but, even on sandy soils, it is now grown extensively, and with much advantage, after either of these crops. The greater part of the wheat crop throughout
A summer fallow once in four, six, or eight years, according to seasons and circumstances, is, however, necessary; and manure should either be applied on that fallow for the first crop or else, I think, preferably, be applied to people thinking of a crop of drilled beans, which ensures the succeeding crop of wheat. If the first crop of beans has been completely cleaned, there is no difficulty in repeating, and even in extending the course; and the crops will be little inferior to those gained at the beginning of the rotation. In manuring the two crops of wheat, one crop of wheat and one of beans are gained from manuring once; when followed every sixth year, three crops of wheat and two of beans are gained from manuring twice; and, when followed every eighth year, four crops of wheat and three of beans from manuring thrice. In the first-mentioned shift, less manure is bestowed than in either of the others; and, if the soil is of good quality, it will support itself; whereas, in the shifts of six and eight, unless foreign manure be procured, it rarely happens that they can go on successfully for any length of time, without abstracting dung from other parts of the farm on which they are practised. [Brown's Tr. on Rural Affairs.]

5016. In cultivating wheat on thin clays, the rotations just mentioned are applicable. A six-course shift of a different kind has, however, been successfully followed by many people; but it requires every advantage that the well-exercised farmer finds at the beginning. 1st, a summer fallow, 2d, double loads per acre; 3d, wheat; 4th, grass; 5th, peas and beans drilled; 6th, wheat. If manure can be given in the middle of the shift, every one of the crops may be expected good; but if that is withheld, there are a number of fallings on the amount of manure which are necessary, in order to regulate their practice according to their means, though it deserves to be remarked, that, however much attention were paid to the collecting of materials which ultimately are converted into manure, many deficiencies in the article would be fully supplied. [Brown's Tr.] A seven-course shift may be comprised in light soils, with the exception of soft sands. Such soils, however, are not constitutionally disposed to the growth of that grain; nor will they, under any management, bear such a frequent repetition of it as those already mentioned. Summer fallow on them may sometimes be necessary; but because of the risk of turnips being executed to be more perfectly executed than even a naked or bare fallow does, may be profitably substituted. Wheat here comes in with propriety after turnips, though, in general cases, it must be sown in the spring months, unless the turnips are stored; in which case it may be sown in November, or in the sixth year, as a way-going crop, after drilled peas and beans, if the rotation is extended to that length. But, take it any way, it is scarcely possible to raise wheat as extensively on light soils, even where there are of the richest quality, as is practicable upon the type of crops of early peas, first or second and the one, resembling them, coughed of the especially more, from the other. To enlarge upon this point would only serve to prove what new husbandmen will dispute, though they, very well, that, on light soils, wheat ought not to be ventured, unless they are either completely clayed or marled; as it is only with the help of these auxiliaries that such a soil can gain stamina capable of producing wheat with any degree of success. [Brown.]

5018. The culture of the soil intended for wheat varies according to its nature, and the preceding and following crops. 5019. On soils really calculated for wheat, though in different degrees, summer fallow is the first and leading step to gain a good crop or crops of that grain. The first fallow should be given before winter, or early spring, and will admit: and some attention should be used to crown the land. If wheat here in comes with propriety after turnips, though, in general cases, it must be sown in the spring months, unless the turnips are stored; in which case it may be sown in November, or in the sixth year, as a way-going crop, after drilled peas and beans, if the rotation is extended to that length. But, take it any way, it is scarcely possible to raise wheat as extensively on light soils, even where there are of the richest quality, as is practicable upon the type of crops of early peas, first or second and the one, resembling them, coughed of the especially more, from the other. To enlarge upon this point would only serve to prove what new husbandmen will dispute, though they, very well, that, on light soils, wheat ought not to be ventured, unless they are either completely clayed or marled; as it is only with the help of these auxiliaries that such a soil can gain stamina capable of producing wheat with any degree of success. [Brown.]

5020. When wheat is sown after beans it rarely happens, in this northern climate, that more than one ploughing can be successfully bestowed. Before this is given, it is advantageous to cross-harrow the land, which level the surface, and permit the ploughing process to be executed with precision. Almost in every case the ridges should be gathered up, so that the harrows may be well cleared out, and the plants preserved from injury during the inclement winter season. Clover land should be neatly ploughed, and well made over, so that the roots of the grasses may be buried and destroyed; for it frequently happens that, after clover is cut, it becomes greatly invaded with weeds, after which it is very difficult to eradicate. In short, sowing wheat after clover on clayey soils in Scotland may be considered as the most hazardous way in which that grain can be cultivated. [Brown's Tr. on Rural Affairs.]

5021. The manures best calculated for wheat, are allowed by all agricultural chemists to be animal matters and lime. The former has a direct influence in supplying that essential constituent to wheaten flour, gluten; and the latter azote and lime, both actually found in the straw of wheat. At all events, it is certain that wheat will not
thrive on any soil which does not contain lime. In this Sir H. Davy, Chaplat, Prof­essor Thac, and Grisenthwaite fully agree.

5022. A more abundant supply of manure is generally required for wheat than for any other grain. Professor Thac says it absorbs more nourishment from the soil than any of the corn tribe; and he calculates that the usual quantity of 100 parts of labour in carting a crop of wheat is 40 will be carried off by the crop. (Principes Rationnels, tom iv. art. Fruits.) At the same time, too large a dose of manure on land in good till is very apt to cause the crop to lodge; and hence some people think it improper to dung rich clays or loams when followed, and choose rather to reserve that restorative to the soil, which is much needed for a crop of oaks, hols be made before they are sown. But the process for a year is attended with many advantages; because good land, fully wrought, contains such a principle of action within itself, as often causes the first wheat crop to be lodged before it is tilled; under which circumstances a much larger proportion of nourishment is before all other things, had, however, attended with disadvantages; because, when dung is kept back to the end of autumn or be­ginning of winter, to be laid on the stubbles, the weather is often so wet that it cannot be carted on with the labour in laying in a soil in making the straw; thin clays, or even upon soils of the other description not in high condition, there can be no doubt but that the end of summer, and upon summer fallow, is the most proper time for manuring, though it will be found, that an improvized expenditure of dung on such occasions ought always to be steadily avoided. (Brit.)

5023. Where manure is abundant, it is stated by some that wheat alternating with a green crop, or indeed any corn crop and a green crop, may be grown alternately for an indefinite time. (Farm. Mag. vol. xxiii. p.298.) It is alleged by others, that this doctrine is not supported by experience. Constant tillage, they say, wears out the best soils, and the grain degenerates in quality, if not in quantity too. Instances, however, are given in The Communications to the Board of Agriculture of potatoes and wheat having been grown alternately on the same soil for a number of years, and very good crops produced. It may be useful to know that the thing is not impossible.

5024. The climate required to bring wheat to perfection must be such as affords a dry and warm season for the blossoming of the car, and the ripening of the grain. Wheat will endure a great deal of cold during winter, if sown in a dry or well drained soil; and if it be covered with snow. Hence it is that wheat is sown as far north as Petersburg and in Sweden. Moderately moist weather before the flowering season, and after the grain is set or formed, is favourable to wheat; but continued heavy rains after the flowering season produce the smut. The dry frosty winds of February and March, and even of April in some districts are injurious to the wheat of Britain than any other description of weather. Unfrost, when the plant is in the ear, produces thin ears; and mildew often result from or follow sultry winds and fogs. Cold, in the blossoming and ripening season in July, even unaccompanied by wind or rain, produces an inferior grain, greatly deficient in gluten; and neat the contrary. The most valuable wheat of Europe, in this respect, is that of Sicily; which Sir H. Davy found to contain much more gluten than the best wheat of Britain.

5025. The season for sowing wheat on clays is generally the latter end of autumn; on early turnip soils it is sown after clover or turnips, at almost every period from the beginning of September till the middle of March; but the far greater part is sown in September and October. For summer wheat, in the southern districts, May is sufficiently early, but in the north, the last fortnight of April is thought a more eligible seed-time. In the cultivation of spring-sown winter wheat, it is of importance to use the produce of spring-sown grain as seed, as the crop of such grain ripens about a fortnight earlier than when the produce of the same wheat winter-sown is employed as spring seed. (Encyc. Brit. art. Agr.)

5026. Seed wheat is prepared for sowing by the process called pickling. According to Brown (Treatise on Rural Affairs, art. Wheat), this process is indispensably necessary on every soil; otherwise smut, to a greater or less extent, will, in nine cases out of ten, assuredly follow.

5027. Though almost all practical farmers are agreed as to the necessity of pickling, yet they are not so unanimous as to the mode operandi of the process, and the article which is best calculated to answer the intended purpose. Stale urine may be considered the safest and surest pickle; and where it can be obtained in a sufficient quantity, it is commonly resorted to. The mode of using it does not, however, seem to be agreed upon; for, while one party contends that the grain ought to be steeped in the urine, another party considers it sufficient to sprinkle the urine upon it. Some, again, are advocates for thoroughly steeping the grain in a pickle made of salt and water, sufficiently strong to buoy up a fresh egg. But whatever differs, there may be a kind of pickle that ought to be used, and the mode of using it, all admit the utility of mixing the wetted seed with hot lime, fresh slaked; and this, in one point of view, is absolutely necessary, so that the seed may be equally distributed. It may be remarked, that experience judiciously applied will be the only resource; for, in every province, not attention is exercised in the contamination of the danger from the first; for if the seed steeped in urine is not immediately sown, it will infallibly lose its vegetative power. The second, viz. sprinkling the urine on the seed, seems to be the safest, if performed by an attentive hand; whilst the last may do equally well, if such a quantity of salt be incorporated with the urine as the grain shall not be salted, that may also be carried in with the seed; the last mode is often accompanied with smut, owing no doubt to a deficiency of strength in the pickle; whereas a single head with smut is rarely discovered when urine has been used.

5028. The mode of pickling wheat that for sowing has recently been adopted in the south of Scot­land, and followed with great success. It is thus described:—"Take four vessels, two of them smaller than the other two, the former with wire bottoms, and of a size to contain about a bushel of wheat, the latter large enough to hold the smaller within them. Fill one of the large tubs with water, and stir and knead the grain in the water, that floats above, and renew the water as often as is necessary, till it comes off almost quite clean. Then raise the small vessel in which the wheat is contained, and repeat the process with it in the other large tub, which is to be filled with stale urine; and in the mean time wash more wheat in the water tub. When abundance of water is at hand, this operation is by no means tedious; and the wheat is much more effectually cleansed from all impurities, and freed more completely from weak and unhealthy granian seeds of weeds, than can be
PRACTICE OF AGRICULTURE.

PART III.

done by the winnowing machine. When thoroughly washed and skimmed, let it drain a little, then empty it on a clean floor or in the cart that is to take it to the field, and sift quick-like upon it, turning it and mixing it with a shovel till it be sufficiently dry for sowing." (Supp. E. Brit. art. Agr.)

5029. The quantity of seed necessarily depends both on the time of sowing and the state of the land; land sown early requiring less than the same land when sown in winter or late. But poor land being at all times in need of seed rich. The quantity accordingly varies from two bushels, or less, to three, and sometimes even to four, bushels per English statute acre. Winter wheat, when sown in spring, ought always to have a liberal allowance, as the plants have not time to tiller much without unduly retarding their maturation. (Supp. & c.) Upon well prepared lands, if the seed is distributed equally, it can scarcely be sown too thin; perhaps two bushels per acre are sufficient; for the heaviest crops at autumn are rarely those which show the most vigorous appearance through the winter months. Bean stubbles require more seed than summer follow; because the roughness of their surface prevents such an equal distribution; and closer layers ought to be still thicker sown than bean stubbles. Thin sowing in spring ought not to be practised, otherwise the crop will be late, and imperfectly ripened. (Brown.)

5030. The modes of sowing wheat are either broad-cast, drilling, ribbing, or dibbling. The first mode is by far the most general, more especially in the north of England and Scotland, and the seed is for the most part covered by the harrows. No more harrowing, Brown observes, should be given to fields that have been followed than what is necessary to cover the seed, and level the surface sufficiently. Ground which is to lie in a broken-down state through the winter, suffers severely when an excessive harrowing is given, especially if it is incumbent on a close bottom; though as to the quantity necessary none can give an opinion except those who are present.

5031. Ploughing in. Many farmers allege that wheat which is harrowed in is apt to be thrown out in spring; or if not thrown out at that season, that it does not tiller well, and that the stalks are apt to dwindle away and fall down in the flowering season. It is certain that this is the case in many parts of England, and the cause assigned by the northern farmers is the defective manner in which the land is ploughed, by which there is not sufficient covering for the seed. To guard against these evils, a very general practice in most of the southern counties, when wheat is sown broad-cast, to plough it in with a shallow furrow. This is done even after beans and on clover leys, and is a favourite practice on very extensive farms in Norfolk and Lincolnshire.

5032. Drilling, however, is extensively practised in some districts, and is becoming more general on lands infested with the seeds of annual weeds, especially when sown in spring. A machine which sows at three different intervals according to the farmer's wish, at the amount of the hole, or, nine inches, is much approved of in the northern districts. It deposits six, seven, or eight rows at once, and allows to its adjustment to one or other of these intervals, and the work is done with ease and accuracy when the ridges are previously laid out of such a breadth (twelve feet and a half) as to be sown by one boat; the machine guided by such a ridge on the other, and its wheels being guided by the very same wheels, which thus always runs in the open furrow between the ridges. If the ten and a half inch interval be adopted, and it is the most common one in that country, the machine sows seven rows at once, or fourteen rows on a ridge of twelve feet and a half. But the space between the rows varies in some parts still more than this machine admits of; it ought not, however, to be so narrow as to prevent hand-hoeing, even after the crop has made considerable progress in growth; and it cannot advantageously be so wide as to admit the usage of any effective horse-hoe.

5033. Sowing is a most convenient mode of sowing common in some places, by which a drill machine is dispensed with, though the same purpose is nearly answered. This we have already adverted to in the section on tillage. The seed is scattered with the hand in the usual broad-cast manner, but as it necessarily falls for the most part between the ridges, and the crop rises in straight and parallel rows, as if it had been sown by a drill machine; after sowing, the ridges are levelled by harrowing across them. This plan has nearly all the advantages of drilling in, as far as it regards exposure to the rays of the sun, and the circulation of air ament to the plants; but as some plants always rise between the rows, it is not quite so proper when hoeing is required. (Supp. E. Brit.)

5034. The dibbling of wheat is practised in some parts of Norfolk. The furrow is laid over flat, and a row of holes is made along the middle of each by a man who uses a dibber in each hand. A muddling workman will make four holes in a second. One dibber is sufficient for three droppers; whence one man and three children are called a set. The dibber carries on three flags or turned furrows; going on some yards upon one of the outside furrows, and returning upon the other, after which he takes the middle one; and thus keeps his three droppers constantly employed; and at the same time is in no danger of filling up the holes with his feet. The dibber makes two or three grains of wheat into each hole; but much time and patience is necessary to teach them to perform the business properly and quickly. An expert dibbler will hole half an acre in a day; though one third of an acre is usually reckoned a good day's work. The seed is either of a bush harrow, or one bushel is cast from one of the common hand machines. It is particularly to be observed of wheat seeds, unless dibbled very thick; which, indeed, may probably be the case, as the weeds are thus allowed a greater space to vegetate in. Marshall's is of opinion, that the dibbling of wheat appears to be peculiarly adapted to deep rich soils, on which three or four grains dibbled early may spread sufficiently for a full crop; whereas light, weak, shallow soils, which have lain two or three years, or some grasses have become established on them, have consequently an addition of labour, otherwise the plants are not able to reach each other, and the grasses of course find their way up between them, by which means the crop is injured, and the soil rendered foult. It is according to the single and sounder grain that good size seed in each hole and no more, there might be an advantage in dibbling, where it could be accomplished at a moderate rate, but where two or three grains are put in each hole, and often six or eight, the source of profit is diminished or destroyed by twofold means; first, by using too much seed to each hole, and secondly, because three or four grains sprouting out of one hole will not make such a strong plant or shoot as one sound grain. In short, making these remarks, we are informed, that an inquisitive farmer himself dibbled a great many holes, and dropped carefully one, two, three, &c. to ten grains of wheat in each hole. He carefully gathered the wheat, and put the produce of all the one grain holes, and of the two grain holes, and of the three, and so on to the ten, apart: on clearing the ten portions, those holes which had three, four, and five grains were decidedly the heaviest produce; and he reasonably concluded that three, four, and five grains were the properest number to drop into each hole. To attempt dibbling either wheat or beans by hand on a large scale, we
WHEAT.

consider quite unsuitable to the present improved state of agriculture; but it may sometimes happen, that on rich loamy land, especially in a showery season, there may be no other way of getting in the seed.

5035. The after-culture of wheat, or culture of the growing crop, depends on the manner in which it has been sown.

5036. When wheat is sown broadcast, the subsequent culture must generally be confined to harrowing, rolling, hand-weeding, or hand-hoeing with a pronged hoe. As grass seeds are frequently sown in spring on the excreta of the herd, much care is employed to leave the surface of the soil as smooth as possible after these operations, to a certain extent, and at the proper season, are found beneficial to the wheat crop itself, and are sometimes performed even when grass seeds are not to be sown. One or two courses of harrowing must be given to all the tenacious soils, and operate like hand-hoeing in raising a fresh mould to the stems of the young plants. Rolling in spring ought never to be omitted on dry porous soils, which are frequently left in so loose a state by the winter frosts, that the roots quit the soil and perish; and, if the land is roughly rolled, the roller has a still further influence over the rootlets, and is of great service in raising the inert masses, and extending the pasture of the plants. Hand weeding, so far as to cut down thistles and other long weeds, is never neglected by careful farmers; but the previous culture ought to leave as little as possible of this work to be done when the crop is growing. (Supp. 1.)

5037. Where drill sowing is practised, the interior of the drills may be hoed or stirred either by hand-hoes, common or pronged, or by horse-hoes or drill harrows. In general, the drill used at sowing will, by the changes it admits of in its double character of drill and horse-hoe, be the best to use for hoeing or stirring; or if a single drill should have been used, the expending horse-hoe, or Wilkie’s brake harrow, may be successfully adopted. The operation of hoeing or stirring should generally be performed in March, and need not be repeated. When grass seeds are to be sown among the wheat, the hoeing is an excellent mode of covering them. Weeding the rows should not be neglected, nor delayed later than the beginning of June.

5038. Where wheat rises too thin in some places, and too thick in others, whether in rows or broadcast, the practice of transplanting from the latter to the former has been recommended. This is said to be practised occasionally in Essex and Norfolk, and the time is the end of March. To be attended with success the soil must be in a good state, and the blanks to which the plants are to be transplanted must be stirred up with a two or small two-pronged fork. Under such circumstances we have no doubt of the plan being attended with success; but we are certain that without stirring the soil, the operation will not answer. Blanks and trenches should be passed over by sowing summer wheat, dibbling beans, or flax, but these are obviously bad modes; a better is either to stir the soil well, by the hand pronghoe, and encourage the tillering of the plants, or to stir the soil and then transplant.

5039. Sowing recommended in certain cases, where the land is not in a sufficient state of fertility or preparation to bring the crops to perfection. Substances of both the solid and fluid kinds have been made use of for this purpose; the first consist chiefly of the dung of different sorts of birds, after being brought into a powdery state, bone-dust, soot, peat ashes, and various saline matters. The latter are principally the drainings of dung-heaps and similar liquid materials. The former should be thinly sown over the crop with as much evenness as possible, as early in the spring as horses can be admitted upon the land without injury; and if it can be done when the weather is inclined to be moist, it is the better. The solid dung with advantage should be passed over the crop with advancing the time; but it should be always taken that the plants be not injured by having too large a quantity applied to them. In this practice the expense should be a primary consideration, and small trials first made where dungs have not been used. The proper season for performing the business is the beginning of February.

5040. When wheat appears too forward and incurvatum, it is sometimes cut down in April with sheep or even with horses, but this requires great judgment to be effected without injuring the crop.

5011. In harvesting wheat, the best farmers both of Britain and the continent agree, that it ought to be cut before it becomes dead ripe. When this is the case, the loss is considerable, both in the field and stack-yard; and the grain, according to Professor Thacker, produces a less white flour.

5042. In ascertaining the proper state, Brown observes, it is necessary to discriminate between the ripeness of the straw and the ripeness of the grain. For, in his opinion, the straw should be ready, under all circumstances, to the eye, to the touch, and to the hand; whereas the presence of the grain, if not immediately visible, may be inferred from the dead weight of the straw. This is contrary to the practice in our island. The straw in this country is not considered ripe until the grain is seen by the eye, and has been deprived of the tough, green coating by which it is distinguished; whereas the former is a necessary part of the crop, but the latter is only a casual appendage. The grain is not perfectly ripe in this country when the ears are cut down, but is left standing in the field. The grain, when perfectly ripe, is dead dry, and on this account bursts the ear easily. When the grain is not dry, the ears stick to one another until after they are gathered; hence it is evident it is not ripe. It is the same with the straw; when it is dry, it is dead, and breaks with a click; if not, the ears stick together and are difficult to separate.

5043. The mode of reaping wheat is almost universally by the sickle. When it is cut by reapers, the straw must be neatly thatched, and the sheaves properly tied with straw. In the latter case, two rows of six sheaves are made to stand in such a manner as to be in contact at the top, though in order to admit the circulation of air they are placed at some distance along this line; and the sheaves are more placed as a covering, the corn end of both being towards the extremities of the line. In a few days of good weather the crop is ready for the barn or stack-yard.

3 G
and small lateral ones to communicate with it. In the best cultivated counties the use of large barns for holding the crop is disapproved of, not only on account of the expense, but because corn keeps better, or is less exposed to damage of any kind, in a well-built stack.

5044. The threshing of wheat, before machines for that purpose were introduced, was an arduous and difficult task. The expense was very considerable; whilst the severity of the labour almost exceeded the power of the strongest man, especially in unfavourable seasons, when the grain adhered pertinaciously to the car, and could not, without difficulty, be completely loosened and removed. In such seasons, expense was the smallest consideration which influenced the husbandman; it was the quantity of grain unavoidably lost which occupied his attention; and, as it appeared difficult to find out a remedy, most people considered it as an evil which could scarcely be avoided. In short, the loss was great in almost every case, but greater with wheat than with any other grain. Every thing of this nature, however, may be prevented, now that threshing machines are introduced, provided the feeder is careful, and proportions the quantity on the board to the strength of the impelling power. Wheat, in fact, is now the cleanest threshed grain; because the length of the straw allows it to be properly beat out before it passes the machine, which sometimes is not the case with short oats and barley. If horses are used as the impelling power, thin feeding is necessary, otherwise the animals may be injured; but where wind or water is employed, the business of threshing is executed speedily, completely, and economically. (Brown.)

5045. In performing the operation, one man feeds the grain in the straw into the machine, and is assisted by two half-grown lads, or young women, one of whom pitches or carries the sheaves from the hay close to the threshing-stage, while the other opens the bands of every sheaf, and lays the sheaves successively on a small table. The car, or forecar, is then loaded, and the car is drawn by two horses, who have threads thrown over them in succession by the fluted rollers, to undergo the operation of threshing. In the opposite end of the barn or straw-house, into which the rakes or shakers deliver the clean-threshed straw, one man forks up the straw from the floor to the straw-mow, and two lads, or young women, build it and treat it down. In a threshing-machine, worked by water or wind, this is the whole expense of hand labour in the threshing part of the operation, and, as a powerful machine can easily thresh from two to three hundred bushels of grain in a working day of nine hours, the expense is exceedingly small indeed. Assuming two hundred and fifty bushels as an average of the work of these people for one day, and their wages to be nine shillings, the expense does not amount to one halfpenny for each bushel of grain. Even reducing the quantity of grain threshed to one hundred and fifty bushels, the easy work of a good machine of inferior size and power, the expense does not exceed three farthings the bushel. But the whole of this must not be charged against the threshing only, the grain being half-dressed at the same time, by passing through one winnowing-machine, which is always attached to a complete threshing-mill; and where a second can be conveniently connected with it, as is commonly the case if the mill is of considerable power, the corn comes down nearly ready for market; so that the threshing, dressing, and building of the straw, with the use of a powerful water-mill, will scarcely cost more than dressing alone when the flail is employed; after every reasonable allowance for the interest of money, and the tear and wear of the machine.

5045. The produce of wheat must of course vary, according to the soil, climate, culture, and kind grown. Professor Thaer says, that in general it gives double the weight of straw that it does of grain; on elevated grounds something less; and on low grounds something more. The yield of wheat in some seasons has been under twenty, while in others it is upwards of thirty bushels the acre, the soil and culture being in every respect the same. The average produce of Britain has been estimated at three, three and a half, and four quarters; and one of the largest crops ever heard of, at ten quarters, and the least at one quarter and a half. The proportion in which the corn bears to the straw, in Middlesex, is eleven and a half bushels to a load of thirty-six trusses of thirty-six pounds each, or eleven and a half cwt.; no great deviation from Professor Thaer's general estimate, a bushel of wheat weighing about 60 or 61 pounds.

5048. To judge of a sample of wheat, examine by the eye if the grain is perfectly fed or full, plump and bright, and if there is any adulteration proceeding from sprouted grains, smut, or the seeds of weeds; and by the smell, if there is any improper impregnation, and if it has been too much heated in the mow or upon the kiln; and finally, by the feel, to decide if the grain is sufficiently dry, as when much loaded with moisture it is improper for the uses of the miller and baker. In cases where a sample handles coarse, rough, and does not slip readily in the hand, it may be concluded not to be in a condition either for grinding or laying up for keeping. When mellilot and wild chamomile abound among the wheat crop, are reaped with it, and undergo fermentation in the rick, the grain will have the flavour of these strong smelling plants. To detect this in the sample, hold the grain close in the hand, moisten it with the breath, and then smell or taste it. This is the practice at Ampthill and other markets in Bedfordshire.
5049. The yield of wheat in flour is, on an average, thirteen pounds of flour to fourteen pounds of grain. In the chemical analysis of wheat, Sir Humphry Davy found that one hundred parts of good full-grained wheat, sown in autumn, yield of starch seventy-seven, and of gluten nineteen; one hundred parts of wheat, sown in spring, seventy of starch, and twenty-four of gluten. American wheats he found to contain more gluten than the British; and, in general, the wheat of warm climates to abound more in gluten and in insoluble parts, and to be of greater specific gravity, harder, and more difficult to grind.

5050. The uses of wheat in the baking, culinary, and confectionary arts are well known. It is also used for making starch, by steeping the grain and then beating it in hempen bags. The mucilage is thus mixed with the water, produces the acetoxy fermentation, and the weak acid thus formed renders the mucilage white. After settling, the precipitate is repeatedly washed, and then moulded into square cakes and kiln-dried. In drying, the cakes separate into flakes, as in the starch of the shops. Starch is soluble in hot water, but not in cold; and hence, when ground down, it makes an excellent hair powder. Its constituents are: carbon, 43.55; oxygen, 49.68; and hydrogen, 6.77 = 100.

5051. The uses of wheat straw are various and well known. As fodder it is, according to Professor Täuber, the most nourishing of any; and it makes the best thatch: it is generally preferred for litter, though rye and barley straw are softer: it is used for making bee-hives, horse collars, mattresses, huts, boxes, baskets, and all kinds of what is called Dunstable work; for the cider press; and, among other things, for burning, to procure potash from the ashes. The straw of wheat from dry chalky lands is manufactured into hats for both men and women. For this purpose, the middle part of the tube, above the last joint, is taken; and, being cut into a length of eight or ten inches, is split in two. These splits are then plaited, by females and children, into various kinds of plait or ribands, from half an inch to an inch broad: these, when sewed together according to fancy or fashion, form different descriptions of ladies' bonnets, and the commoner plait and coarser straw of men's hats. The hats are whitened by being placed in the vapour of sulphur. Leghorn hats are made from the straw of a bearded variety of wheat, which some have confounded with rye. It is cultivated on the poorest sandy soils in the neighbourhood of the Arno, between Leghorn and Florence, expressly for this manufacture. It is of humble growth, and not above eighteen inches high; is pulled up when green, and bleached white by spreading and watering on the gravelly banks of the Arno. The straws are not split; but in other respects the manufacture into ribands is the same as at Dunstable in England and in the Orkney Islands.

5052. The Leghorn manufacture of wheat straw into the well-known hats has lately been enquired into, and detailed in several publications. The variety of wheat cultivated in Tuscany for this purpose is known as the grano marzuolo, or marzolano, a variety of summer wheat with long bearded ears. It is cultivated on the sand of the valley of the Arno. The seed is sown in March, very thick, and pulled when the ear is fully shot, but before the grain is formed. It is then 18 inches high, if the crop is good; it is bleached as we do flax, and afterwards tied up in bundles in the same manner, and carried home, to have the part between the ear and the first fruit in the stalk selected, that being the only part used. (Gard. Mag. vol. v. p. 77.)

5053. To obtain the whiteness so much prized, the straw is smoked with sulphur previously to being worked; the plait is also smoked; and, lastly, the hat. About Sienna the process is simply a little sulphur being placed on bunches of the straw being placed on loose hazel rods, and the smoke being spread over them, and the plait being pulled up into hats by women, who do nothing else; it is not put together by edges, nor overlapped. On the operation of pressing, a great deal depends: there are only two good machines for that purpose in the country. Such is the practice for procuring the hat straw, which they sow for seed is in other ground: not one fourth of the seed is used, and the grain is allowed to come to maturity in the usual way. It is said to be a capital wheat for vernicelli, macaroni, &c., and also for making into bread. (Gard. Mag. vol. v. p. 71.)

5054. The straw for use is classed or stapled like our wool. Children or inferior hands work the coarse, thick straw, while good hands work the fine only. Whether fine or coarse, it is only the part on which the spike grows that is made use of; and it is always the same plant, consisting of thirteen straws, which is worked. In the fine plait there is a very great waste of straw, as they reject all that is in the least too thick, and they cut off a considerable part of the straw when it comes near the flower-spike. Fine plait is not accounted good unless very much drawn together; for which end it is worked very wet. The bunches of straw are always put into a small jar, filled with cold water, which stands beside the plaiter. After being smoked and pressed, it is made up into hats by women, who do nothing else; it is not put together by edges, nor overlapped. On the operation of pressing, a great deal depends: there are only two good machines for that purpose in the country. Such is the practice for procuring the hat straw, which they sow for seed is in other ground: not one fourth of the seed is used, and the grain is allowed to come to maturity in the usual way. It is said to be a capital wheat for vernicelli, macaroni, &c., and also for making into bread. (Gard. Mag. vol. v. p. 71.)

5055. The mode of plaiting is as follows: — The straws being picked, and put into separate bundles, according to their quality, let thirteen of them be taken and tied firmly together by the seed ends; attach them at every thing that is as the back of a chair, to keep them steady; then take hold of the loose end of the bundle, putting six straws into the one hand, and seven into the other. Take the outermost, and with it cross over two; then carry it behind the next two; and lastly, before the remaining two; after which lay the straw into the other parcel of six. The first parcel of six being now made seven, take the outermost straw of it, and carry it across the bundle, by two, as in the former case, laying at last this seventh straw into the outer parcel as before. It will be understood by this, that the outermost straw of each parcel is always made the acting straw, and that, in the progress of the operation, each of the straws of both parcels is thus employed in its turn.

5056. As the work goes on, it will be necessary now and then to join in new straws. Seeing any one needing to be renewed, watch until it becomes the acting straw; and, when it is to be laid into the other parcel, after performing its round, lay it up over the piece of plait, instead of putting it into the
PARCTCE OF AGRICULTURE. PART III.

5063. The **diseases of wheat** are the rust, smut, or black mildew, the latter including what is vulgarly called blight. These have been already treated of in our view of the vegetable economy, and we shall merely offer a few practical observations on the smut and mildew.

5064. The **proximate cause of smut**, in whatever manner the smut may be transmitted from the seed plant to the wheat, is in general, that it is dropped in the smut-ball, which B. de Jussieu first conjectured to be Lycoperdon globsum, and which M. Prevost ascertained to be a microscopic vegetable of some sort; and that though the most careful washing, even with the application of caustics, may not in every case insure against smut, yet if the seed be prepared in the manner already mentioned, the disease will never prevail to such a degree as materially to injure the crop. This is all that cultivators need to know, and all, perhaps, in the present state of science, that can be known, of the cause and prevention of smut. See an article at length on this subject in the British Farmer’s Magazine, vol. ii. p. 176.

5065. Mildew is a much more destructive distemper than smut; and, as it is probably occasioned by a peculiar state of the atmosphere during the periods of flowering and ripening, it is likely to beset all attempts at prevention. The prevalence of heavy fogs or mist, dazzling rains, and sudden changes in the temperature, have been assigned as the causes of mildew; and it has been found that such exposures are much less affected than low sheltered lands, in years when mildew prevails most generally, the disorder may perhaps be somewhat diminished by drilling, which admits a freer circulation of air. Spring or summer wheat is less liable to mildew than the winter species, though it does not always escape. Minute parasitical Fungi, Puccinia Graminis (Enc. of Plants), are commonly detected on the straw of mildewed wheat; and there cannot be the least doubt that the barberry bush, and probably several other shrubs on which these Fungi abound, have a powerful influence in communicating the disease to a certain distance. (Sir Joseph Banks on Fycmen, and Comm. to the B. of Agr., vol. ii. p. 438.)

5066. The **wheat fly** has, of late years, been one of the greatest enemies to the wheat crop in Scotland. In North America this insect, or one of the same family, has been known for many years, more especially in the eastern states, and there are destructive ravages and new attacks every year. The name of the Hessian fly. In the modern nomenclature, the Rev. W. Kirby informs us that the wheat fly, formerly the Tylpa tritici Linnaeus, is now the Cecidomyia tritici (fig. 724a), and the Hessian fly the C. destructor (b). The wheat fly generally makes its appearance about the end of June; and, according to the observations of Mr. Shirreff, they exist throughout a period of thirty-nine days. The hue of the fly is orange, the wings transparent, and changing colour according to the light in which they are viewed. It lays its eggs within the glumes of the florets, in clusters varying in number from two to ten, or even fourteen; and the larva feed upon them generally. "They are peculiar in the eggs in the course of eight or ten days: they are at first perfectly transparent, and assume yellow colour in a few days afterwards. They travel not far from the straw to another, and forty-seven have been numbered in one. Occasionally there are found in the same floret larvae and a grain, which is generally shrivelled, as if deprived of food, and although the pollen may furnish the larvae with food in the first instance, they soon crowd around the lower part of the grain, and there, in all probability, subsist on the matter remaining to form the grain." (Mag. Nat. Hist. vol. ii. p. 450.) The larvae are preyed on by the Ceraphron destructor, an ichneumon fly, which deposits its eggs only once, without being covered for preventing the total destruction of the wheat crop attacked by the Cecidomyia. Mr. Shirreff, speaking of this ichneumon, says, "I could not determine if it actually deposits its eggs in the maggot’s body; but there can be no doubt, for I have often seen the maggots when the ichneumon has left the maggot, and the maggot has not been attacked, repeatedly, it is probable the fly delights to deposit the maggots, as well as to deposit eggs in their bodies. The carawg, also, devours the maggots as food. (Brit. Farm. Mag. vol. iii. p. 498.) Mr. Gorrie estimates the loss sustained by the farmers interested in the Carawg in the amount of one-third of the wheat crop, at 6500, in 1827, at 25,000l. in 1828, and at 54,000l. in 1829. (Perth Miscellanies, vol. i. p. 42.)" The same writer, in May 1836, thus depicts the prospect of the wheat crop in the Care of Gorrie:—"The Cecidomyia is still alive in formidable legs. That the flies will this season be as in great plenty as ever, is now quite certain; that they will lay their eggs on no other plant than those of the wheat genus, is also true; the only chance of escape is in the time the pupa appear the fly state. Should this sunny weather bring them forward within a fortnight or three weeks from this date, the greater part will have perished before the wheat is
in the ear; or should the earing take place before the flies appear, then only the late or spring-sown wheats will suffer; but these appear slender chances. We know the history and habits of the insect too well to believe that either mist, or rain, or dew, or drought, will either forward or retard their operations, if the main body appear about the time the wheat comes in the ear. In addition to that vile gust, our neighbours in the Lobians are threatened with a no less formidable invader in the A'scius paludis-
rinus, which, as we are informed on respectable authority, have already commenced their depredations, and are thinning the wheat plants rather liberally in that quarter. It, like the Hessian fly in America, attacks the under joints, which become habitations for the young larvæ. As far as our observation extends, this pest has not yet reached us in noticeable numbers." (Country Times, May 17, 1836.)

5067. The culture of summer wheat differs from that of winter or spring-sown winter wheat, in its requiring a more minutely pulverised and rather richer soil. It need not be sown sooner than April, and it advances so rapidly to maturity that it hardly affords time for hoeing (if sown in rows), or harrowing and rolling. When grass or clover seeds are sown on the same ground, they are sown immediately after the wheat, and harrowed in with a light harrow or rolled in. In this respect, and indeed in all others, the preparation of the soil and sowing of this grain are the same as for barley.

5068. The produce of summer wheat, both in grain and straw, is considerably less than that of winter wheat; the straw is only fit for litter or inferior fodder; the flour produced by the grain is rather coarser and darker than that of common wheat. Of course this sort of wheat cannot, as already observed, be recommended for general culture.

SECT. II. Rye. — Secale cereale L.; Triándria Digógia L., and Gramínæ J. Scigle, Fr.; Rogor, Ger.; Segale, Ital.; and Centeno, Span. (fig. 725.)

5069. Rye, according to some, is a native of Crete; but it is very doubtful whether any country can be now ascertained to be its native soil. It has been cultivated from time immemorial, and is considered as coming nearer in its properties to wheat than any other grain. It is more common than wheat on most parts of the continent, being a more certain crop, and one which requires less culture and manure. It is the bread corn of Germany and Russia. In Britain it is now very little grown, being no longer a bread corn, and therefore of less value to the farmer than barley, oats, or peas. Many consider it the most impoverishing of all corn crops.

5070. The varieties of rye are not above two, known as winter and spring rye: but there is so little difference between them that spring rye sown along with winter rye can hardly be distinguished from it.

5071. The soil for rye may be inferior to that chosen for wheat: it will grow in dry sandy soils, and produce a tolerable crop; and, on the whole, it may be considered as preferring sands to clays. The preparation of the soil should be the same as for wheat. According to Professor Thaer, rye abstracts 30 parts in 100 of the nutrition contained in the soil on which it is grown.

5072. The climate for rye may be colder than for wheat; but it is rather more injured by rains during winter, and equally injured by moist weather during the flowering season.

5073. Rye is sown either in autumn or spring, and either broad-cast or in drills: two bushels and a half is the usual allowance when it is sown broad-cast. As it vegetates more slowly than wheat, it should be sown when the soil is dry; a wet soil being apt to rot the grain before it has completely germinated. No pickling or other preparation is given.

5074. The after culture, harvesting, and threshing are the same as for wheat; and the produce in grain is, under similar circumstances, equal in bulk; but in straw it is greater in rye than in any other grain. Sir H. Davy found, in 1000 parts of rye, 61 parts of starch and five parts of gluten. Professor Thaer says rye is the most nourishing grain next to wheat. It contains an aromatic substance, which appears to adhere more particularly to the husk, since the agreeable taste and smell peculiar to rye bread are not found in that which is made from rye flour that has passed through a very fine bolting-cloth; while the fragrance may be restored by a decoction of rye bran in the warm water used to make the dough. This substance, Thaer says, seems to facilitate digestion, and has an action particularly refreshing and fortifying on the animal frame.

*5075. The use of rye is chiefly for bread, especially for gingerbread. It is also used in the distilleries; and the straw is used for the same purposes as that of wheat, except that it is useless as fodder. Some prefer it for thatching and litter, and also for collars-making: it is also employed in Dunstable work. Tanners are said to use it in some districts.

5076. Rye is sometimes sown as a green crop, with a view of affording some keep for sheep early in the spring, and also for being ploughed in as manure; but that husbandry
must be bad or unfortunate which requires recourse to either mode. In some districts it is customary to sow the head lands of wheat fields with rye, which is said to keep poultry from penetrating to the wheat.

507. The manufacture of rye straw into pitail, for hats is a new application, for which the public are indebted to Messrs. J. and A. Muir of Greenock, manufacturers of straw hats in imitation of those of Leghorn. Messers Muir had previously tried rye grass, crested dog's-tail grass, sweet-scented vernal grass, and the straw of wheat, raised both from British and foreign seed, without success. At last the idea of employing rye grass suggested itself to them; and taking advantage of a grant of 100 acres of land in the Orkney Islands founded by an English gentleman about 1830* 1/4 from 40 to 45 bolls, which are sown on about twelve English acres of sandy soil, manured with sea-weed. Several acres of heath, for bleaching, the straw, and water for steam, which latter is produced in the necessary quantity by a water mill, with a pond beginning to form; and it is necessary to attend to the precise time, for ten days too early or too late produce a considerable difference in the look of the straw. When the rye is cut, women are employed to tie it at the lower extremity in handfuls; it is then put into boxes, and covered with boiling water, until this is completed. After this, the straw is turned twice daily, until the bleaching, which takes about ten days, is completed. If exposed to much sun while bleaching, the straw is injured in colour, and rendered very liable to mildew. It is of great importance to have the straw turned at least once, the seed, therefore, having been recently rendered arable; and if the season is at all favourable, it comes into flower in July, when it is cut down. The whole stem is then immersed in boiling water, in a trough made for the purpose, and remains in this state for two hours. When taken out, it is spread upon a grass field, and exposed to the sun, till it is properly bleached, which requires from two to four days, according to the weather. When bleached, the talk is divided into separate parts at each joint, and put up into bundles by the lengths. In this manner, the bundles lie in a proper place till wanted by the plaiters. This last process is done chiefly by old peopling, who are unable for the finer work, or the manufacture of hats who have only lately

5078. *Rye is less subject to disease than most other grain, and is even sown among wheat and round wheat fields from an idea that it will keep off blight and mildew as well as poultry.

5079. *The spur or ergot of rye is by some considered as a fungus, a species of Sclerotium, somewhat analogous to that which produces the smut. It is not peculiar to rye, but it is very seldom found on any other graminaceous plant. "It is a production of the seeds, is long, horny, and cartilaginous; and is sometimes straight, at others curved; sometimes it is found more than two inches in length. The resemblance of this substance to cocks' spurs has given it the name by which it is distinguished. On breaking a spurred seed, you find within it a substance of a dull white colour adhering to the violet skin that surrounds it. Rye thus attacked cannot germinate. M. Tessier remarked that the most rainy years were the most productive of this disease; that the soils on which most spurred rye grew were mostly of such high grounds were nearly free from them, unless when the furrows prevented the water from running freely off, while the lower parts of the same field produced more than the upper parts." (Brit. Farm. Mag. vol. iii. p. 382.)

In France, rye ergot, or the chronical disease of rye, is called the ergot of rye. This disease is also known in Switzerland, where it was observed that most animals refused to eat diseased rye, or rye affected with the cock-spur, as it is called. The Royal Society of Medicine at Paris employed M. Tessier, a distinguished agricultural writer and man of science, to go into the countries where the dry gangrene prevailed, and collect a sufficient quantity of the ergot or cockspur rye for experiments. The result confirmed the opinion of those who attributed the disease to the cause assigned. "France afforded, also, a simple explanation of the fact that persons might live for a considerable time upon rye affected with the cockspur, without suffering any sensible injury from its use; since, in all the animals upon which it was tried experimentally, a given quantity was required to produce the specific effect; and they suggested the only measure, that of separating the diseased from the sound rye, which could prevent so great a national calamity as that which has been so often produced by its use. The naturally occurs in this country, but there are no instances recorded of its producing any such effects as it is said to do in France; but in the Philosophical Transactions, Dr. Wollaston has narrated several cases in which dry gangrene was produced in one family by partaking of damaged wheat; and nearly the same effects were produced in a family in Wiltshire by the Lolium temulentum entering largely into the composition of bread. (Stephenson and Churchill's Med. Bot. art. Scele.) M. Lagasse states that the ergot is covered with a thin pellicle and filled with a grey powder. It is collected in Spain by women and children, who wade in the fields of standing rye for the purpose, and with their utmost vigilance can obtain it, but in very small quantities, in consequence of which it sells high as an article of the materia medica. (Brit. Farm. Mag. vol. iii. p. 158.) Medicinally it is used in uterine diseases.

5080. *Barley, though less calculated for a bread corn than rye, may be considered as next in value to wheat in Britain. Of what country it is a native is unknown. Some assign it to Tartary, others to Siberia, and even Scotland has been mentioned. It has been cultivated from the earliest antiquity, and was much in use among the Romans, both as food for soldiers and horses. In Sweden and Lapland it is more cultivated than any other grain, on account of its requiring to be so short a period in the soil; sometimes not longer than six weeks, and seldom more than seven or seven and a half. In Spain and Sicily they have two crops a year on the same soil: one is sown in autumn and ripens in May, and the other is sown in May and reaped in autumn. In Britain barley is a tender grain, and easily hurt in any of the stages of its growth, particularly at seed time; a heavy shower of rain will then almost ruin a crop on the best prepared land; and in all the after processes greater pains and attention are required to insure success than in the case of other grains. The harvest process is difficult, and often attended with danger; even the threshing of it is not easily executed with machines, because the corn generally adheres to the grain, and renders separation from the straw a troublesome task.
Barley.

5081. Species and varieties. (fig. 726.) There are six species and subspecies of this grain in cultivation besides varieties. These are,—

1. Hordeum vulgare, Spring barley (a).
2. Hordeum distichon, Common or long-cared barley (b).
4. Hordeum distichon, Common or long-cared barley (c).
5. distichon nudum, Naked barley.
6. Zea cirta, Sprat or battufera (d).

The second and fifth sorts are allowed to be subspecies or varieties of the first and fourth, and indeed there can be little doubt that the whole do not constitute more than one species.

5082. The spring barley or early barley (a), Orge carré, Sucrion de printemps, Fr., is distinguished by its double row of beards or awns standing erect, and its thin husk, which renders it favourable for malting. This is the sort principally cultivated in the southern and eastern districts of both England and Scotland, and of which the farmers make two sorts, viz. the common, and the rath-ripe barley; but these two sorts are in reality the same; for the rath-ripe is only an alteration of the common barley, occasioned by being long time sowed upon warm gravelly soils. The seed of this, when sown on cold or strong land, will, the first year, ripen near a fortnight earlier than the seed taken from strong land, and therefore the farmers in the vales generally purchase their seed-barley from the warm or gravelly lands: for, when preserved in the vales two or three years, it becomes full as late in ripening as the common barley of their own product; on the other hand, the farmers on warm lands are also obliged to procure their seed-barley from the strong lands, otherwise their grain will degenerate in bulk or fulness, which by this change is prevented.

5083. The Siberian barley, Orge céréale, Fr., and Humbol cere, Ger., is a variety of early barley with broader leaves, and reckoned more productive than the other. It is much grown in the north of Europe, and was introduced to this country in 1768, but is believed to be now lost or merged in the parent species.

5084. Winter barley, late barley, or square barley (b), Orge carré d'hiver, Ecouyron, Fr., has the grains disposed in four or in six rows, large and thick skinned. It is chiefly cultivated in the north of England and in Scotland, on account of its hardiness; but from the thickness of its rind it is ill adapted for malting, and is going out of use.

5085. Bigg, big, or barley big, is a variety of winter barley known by always having six rows of grains, by the grains being smaller and the rind thicker, and by its being earlier than the parent variety. Professor Martyn says, he has frequently counted forty-two grains on one ear of bigg, when common or long-cared barley had only twenty-two.

5086. Common or long-cared barley (c), is known by its very long spike or ear, flatted transversely, greater in breadth than thickness, with chaff ending in an awn sixteen times the length of the grain. This sort is cultivated in many parts of England and Scotland; though some object to it because the ears being long and heavy they think it apt to lodge.

5087. Naked barley, or wheat barley, Orge nue à deux rangs, Fr., is known by the grain separating easily from the chaff, and by some considered as nothing else than spelt wheat, which it greatly resembles. It does not appear to be cultivated at present in any part of Britain.

5088. Sprat, or battufore barley (d), Orge éventail, Orge-cirta, Fr., is known by its low stature, coarse straw, short broad ears, and long awns. The long awns and closeness of the ears protect it better from birds than most other sorts, but as the straw is scanty and of little use it is not much cultivated.

5089. Besides these sorts there are some local varieties, as Thanet barley, Putney barley, &c., which are merely names given to the varieties common in those places. The Thanet is the winter, and the Putney the sprat barley.

5090. New varieties may be procured by selection or crossing, as in the case of wheat. (5009.)

5091. In choosing a sort of barley for cultivation, regard must be had to the soil and climate. The hardiest may be considered the winter barley, and the earliest, and perhaps the best, is the spring barley. The long-cared is also a much esteemed variety.

5092. In choosing from any particular variety, the best grain for sowing is that which is free from blackness at the tail, and is of a pale lively yellow colour, intermixed with a bright whitish cast; and if the rind be a little shrivelled, it is so much the better, as it shows that it has sweated in the mow, and is a sure indication that its coat is thin. The husk of thick-rinded barley being too stiff to shrink, will lie smooth and hollow, even when the flour has shrunk from it within. The necessity of a change of seed from time to time, by sowing that of the growth of a different soil, as it has been observed, is in no instance more evident than in the culture of this grain, which otherwise becomes coarser and coarser every year. But in this, as well in all other grain, the utmost care should be taken that the seed is full bodied.

5093. The best soil for barley is a light rich loam, finely pulverised. It will neither grow well on a sandy or soft soil, nor on strong clays, such as are suitable for wheat.

5094. The preparation of the soil is sometimes by a naked fallow, but generally by a turnip fallow; sometimes it is taken after peas and beans, but rarely by good farmers either after wheat or oats, unless under special circumstances.
5095. When sow after turnips it is generally taken with one furrow, which is given as fast as the turnips are consumed, the ground thus receiving much benefit from spring frosts. But often two or more furrows are necessary for the fields last consumed; because, when a spring drought sets in, the surface, from being parched by the removal or consumption of the crop, gets so hardened as to render a greater quantity of ploughing, harrowing, and rolling necessary than would otherwise be called for. When sown after beans and peas, one winter and one spring ploughings are usually bestowed; but, when after wheat or oats, three ploughings are necessary, so that the ground may be put in proper condition. These operations, in a warm, moist weather, and an upward wind, are the danger of the business, and for the expense of his labour. Where land is in such a situation as to require three ploughings before it can be seceded with barley, it is better to summer fallow it at once, than to run the risks which seldom fail to accompany a quantity of spring labour. If the weather be dry, and the land has been subject to the different processes, and an impenetrable crust has been formed; if it be wet, the benefit of ploughing is lost, and all the evils of a wet seed-time are sustained by the future crop. (Brown.)

5096. To whatever crop barley succeeds, the harrow and roller, when the plough alone is insufficient, should be resorted to in reducing the soil to a condition suitable for a crop. In most cases more than one earth is given; though, after a winter furrow, the grubber may be used in spring instead of the plough. After turnips, eaten on the ground by sheep, the land, being consolidated by their treading, sometimes receives two ploughings; if only one, it should be well harrowed and rolled; and it is considered finished by harrowing after the roller, especially if grass-seeds be sown, which are covered by this last harrowing. Barley is generally sown on the first ploughing, and covered by a second shallow ploughing. As it is found of great importance, with a view to speedily and equal vegetation, that the ground should be free from weeds; barley is generally sown upon what is termed barley, that is, as soon as possible after it is turned up by the plough.

5097. Measure can seldom be given with advantage to a crop that occupies the soil so short a period as barley, and therefore it generally is sown on land which has been enriched for a preceding crop.

5098. The climate in which barley delights is warm and dry. There are instances of a crop being sown and ripened without having enjoyed a single shower of rain; but gentle showers from the time it is sown till it begins to shoot into the ear, are favourable; while heavy rains at any period, and especially immediately after sowing, or during the blossoming, ripening, and reaping seasons, are highly injurious.

5099. The best season for sowing barley is considered to be from the beginning of April to the middle of May; but bigg may be sown either in autumn to stand the winter, or as late as the first week of June. In England, the winter or four-rowed barley is frequently sown in autumn, and stands the most severe winters. With respect to the lateness at which bigg and summer barley may be sown, much depends on the sort of weather which occurs during the first three weeks after sowing.

5100. When barley is sown late it is sometimes steeped in common water to promote its germination; but it is generally shelled or otherwise prepared. The advantages of steeping are, procuring an equal germination, and consequently ripening, and getting the start of weeds. The following directions are given for performing the operation:—First, take out about one-third of the contents of the sacks of seed barley or rent, and cast it in the bottom of a tub or vessel, to cover the grain to be steeped in clean water; let it be covered with it for at least twenty four hours; when the ground is very dry, and no likelihood of rain for two or three days, it is better to lie thirty-six hours. Sow the grain wet from steeping without any addition. The seed will scatter well as clean water has no tenacity; only the sower must put in a fourth or a fifth more than is usual of dry grain, as the grain is swelled in that proportion. Harrow when thought preferable in as quickly as possible after it is sown; and, though not necessary, give it the benefit of a fresh furrow if convenient. You may expect it up in a fortnight at farthest. (Brown.)

5101. The quantity of seed is different in different cases, according to the quality of the soil and other circumstances. Upon very rich lands, eight pecks per acre are sometimes sown; twelve is very common; and upon poor land, more is sometimes given.

5102. Whether the practice of giving so small a quantity of seed to the best lands is advantageous or the reverse, seems a disputed point among the best farmers. That there is a saving of grain there can be no doubt; and that the bulk may be as great as if more seed had been sown, there can be as little question. Little argument, however, is necessary to prove that thin sowing of barley must be attended with considerable disadvantage; for if the early part of the season be dry, the plants will not only be stunted in their growth, but will not send out offsets; and if rain afterwards fall, an occurrence that must take place some time during the summer, often at a later period of it, the plants begin to steal, and send out a number of young shoots. These young shoots, unless under very favourable circumstances, cannot be expected to arrive at maturity; or if their ripening be waited for, there will be a great risk of losing the early part of the crop, a circumstance that frequently happens. In almost every instance an unequal sample is produced, and the grain is for the most part of an inferior quality. It is therefore usual to sow a quantity of seed sufficient to ensure a full crop, without depending on its sending out offsets; indeed, where that is done, few offsets are produced, the crop grows and ripens equally, and the grain is uniformly good. (Brown on Rural Affairs.)

5103. The modes of sowing barley are either broad-cast, or in rows by the drill or ribbing. The broad-cast mode is almost universally adopted; unless in lands much infested with annual weeds, where drilling and hand-hoeing, and in particular cases horse-hoeing, may be employed with advantage.

5104. The only culture which barley requires while in a growing state, is hoeing and weeding if in rows, and weeding alone if broad-cast. Sometimes barley is rolled to compress a soft soil and exclude the drought, and when very thick it may be first harrowed and then rolled. Grass seeds and clover are sown with the grain before the last harrowing, when the broad-cast mode is adopted; and immediately before hoicing, when the barley is in rows. The former is much the best mode for insuring a strong plant of clover.

5105. Eating down barley, which from winter or very early sowing is over-luxuriant, is practised in some parts of the country. It is believed that what now is much better than feeding it; because the sety takes off only the rank tops, but the sheep feed upon all indifferently; nor should they even, in any case, be left
Barley is ripe when the red ruan, as the farmers term it, meaning a reddish colour on the ear, is gone off; or when the ears droop, and fall, as it were, double against the straw, and the stalks have lost their verdure; but in the latter case it is too ripe.

In the harvesting of barley more care is requisite than in taking any of the other white crops, even in the best of seasons; and in bad years it is often found very difficult to save it. Owing to thebrittleness of the straw, after it has reached a certain period it must be cut down; as, when it is suffered to stand longer, much loss is sustained by the breaking of the heads. On that account it is cut at a time when the grain is soft, and the straw retains a great proportion of its natural juices, consequently requires a long time in the field before either the grain is hardened or the straw sufficiently dry. When put into the stack sooner it is apt to heat, and much loss is frequently sustained.

Barley is generally cut down in England with the cradle scythe, and either tied up or carted home loose after lying in the swath some days to dry. It is not apt to shed; but in wet weather it will be likely to spout or grow musty; and therefore every fair day after rain it should be shaken up and turned: and when it is tolerably dry, let it be made up into shocks; but be careful never to house it till thoroughly dry, lest it mow-burn, which will make it malt worse than if it had spared in the field. It is remarked by Lisle, that poor thin barley should be cut a little sooner than if the same plants were strong and vigorous; as the straw, when the plants are full ripe, in such cases will not stand against the scythe. In this situation, barley in particular should lie in swath till it is thoroughly dry. Some of his barley, which lay out in swath five or six days in very fine weather, though both blighted and edge-grown, grew plump, and acquired a colour almost equal to the best. He reckons short scythes the best for mowing lodged or crumpled corn, because they miss the fewest plants; and observes, that a bow upon the scythe, which is put away the swath before it, is preferable to a cradle, the fingers of which would be pulled to pieces by the entangled corn, in drawing back the scythe. In Scotland and Ireland it is generally reap'd with the sickle, bound in sheaves, and set up in shocks.

Many farmers make an opening in the stack from top to bottom. This opening is generally made by placing a large bundle of straw in the centre of the stack, when the building commences, and in proportion as it rises the straw is drawn upwards, leaving a hollow behind; which, if one or two openings are left in the side of the stack near the bottom, insures so complete a circulation of air, as not only to prevent heating, but to preserve the grain from becoming musty.

The threshing and dressing of barley require more labour than those of any other grain, on account of the difficulty of separating the awns from the ears. For this purpose some threshing machines are furnished with what is called a hummelling machine, already described (2799); and where this is wanting, it is customary to put the grain, accompanied with a portion of threshed straw, a second time through the machine. Where barley has been mown, the whole of the straw requires to be twice threshed, independently of the necessity of getting rid of the awns.

The produce of barley, taking the average of England and the south of Scotland, Donaldson considers, might be rated at thirty-two bushels; but when Wales and the north of Scotland are included, where, owing to the imperfect modes of culture still practised, the crops are very indifferent, the general average over the whole will not probably exceed twenty-eight bushels the acre. Middleton states it as varying in England from fifteen to seventy-five bushels per acre. The average produce of the county of Middlesex, he says, is about four quarters of corn and two loads of straw per acre.

The uses of barley are various. In Wales, Westmorland, Cumberland, and in the north, as well as in several parts of the west of Scotland, the bread used by the great body of the inhabitants is made chiefly from barley. Large quantities of the barley cultivated in England are converted into beer, ale, porter, and what is called British spirits, as English gin, English brandy, &c. The remainder, beyond what is necessary for seed, is made into meal, and partly consumed in bread by the inhabitants of the above-mentioned districts, and partly employed for the purpose of fattening black cattle, hogs, and poultry. There is a much greater share of the Scotch barley consumed in distillation, in proportion to the quantity cultivated, than of the English. Exclusive of what is used for seed, the Scotch barley is either converted into beer or ale; or made into pot-barley, or into malt, for the use of the inhabitants in the more remote and less cultivated parts of the kingdom; or, lastly, into whisky. In The Report of Middlesex it is stated, that much of the most ordinary barley is given to poultry; the rest is sold to the maltsters, except so much as is reserved for seed.

Barley is the great purpose to which barley is applied in Britain. To understand the process of malting, it may be necessary to observe that the cotyledons of a seed, before a young plant is produced, are changed by the heat and moisture of the earth into sugar and mucilage. Malting grain is only an artificial mode of effecting this by steeping the grain in water and fermenting it in heaps, and the arrest of its progress towards forming a plant by kiln drying, in order to take advantage of the sugar in distillation for spirit or fermentation for beer. The grain of barley contains starch and sugar; and the chemical constituents of both these ingredients are very nearly alike. In the process of malting, a portion of the starch is converted into sugar, so that the total quantity of sugar, and consequently the source of spirit, is increased by the transformation.

To choose a proper sample of barley for malting, observe the directions given for choosing seed barley. (5691)
5115. Of pot-barley there are two sorts, pearl and Scotch; both are produced by grinding off the husk, and the pear barley is produced by carrying the operation so far as to produce roundness in the kernel. It is used in soups, gruels, and medicinal drinks.

5116. Barley meal is ground like oatmeal or flour; the coarser sort, with the bran, is used for fattening live stock, especially pigs and poultry; but fine boiled barley flour, made into a thin pottage or pudding, and spread out in thick cakes, and toasted on a hot plate of metal, forms a light breakfast bread, much esteemed in some parts of Scotland. It is served in a recent state, hot, and spread with butter and honey, and eaten in several folds. Two parts of barley flour, one of wheat flour, and one of rye, are said to make a light and very agreeable leaf of bread.

5117. The produce of barley in flour is 12lbs. to 14lbs. of grain. Sir H. Davy found 1000 parts of barley meal to afford 950 parts of soluble or nutritious matter; viz. 790 of mucilage or starch, 70 of sugar, and 60 of gluten.

5118. Barley straw is chiefly used for litter and packing; it is unfit for thatch or rope-making, and of little value as fodder.

5119. The diseases of barley are few, and chiefly smut, but of quite a different species from that which affects the wheat, and one which it is found cannot be prevented by picking and lining.

5120. The out is a very useful grain, and more peculiarly adapted for northern climates than either wheat, rye, or barley. Its native country is unknown, unless the wild oat be considered as the parent species, which is highly probable. The culture of the oat in France is chiefly confined to latitudes north of Paris. It is scarcely known in the south of France, Spain, or Italy; and in tropical countries its culture is not attended to. In Britain it has long been very generally cultivated, formerly as a bread corn, but now chiefly as horse-food. Of all the grain this is the easiest of culture, growing in any soil that admits of ploughing and harrowing.

*5121. The varieties of oats are more numerous than those of the other grains, and some of them are very distinctly marked. The principal are as follows: ---

5122. The white oat or common oat (fig. 727, a), Avene blanche, Fr., in most general cultivation both in England and Scotland, and known by its white husk and kernel.

5123. The black oat, Avene à grappe noir, Fr., known by its black husk; cultivated on poor soils, in the north of England and Scotland.

5124. The red oat, known by its brownish red husk, thinner and more flexible stem, and firmly attached grains. It is early, suffers little from winds, meals well, and suits windy situations and late climates. It is understood to have originated in Peebleshire, on the estate of Magsuchill, by which name it is sometimes known.

5125. The Poland oat, known by its thick white husk, amless chaff, solitary grains, short white kernel, and short stiff straw. It requires a dry warm soil, but is very prolific. The black Poland oat is one of the best varieties; it sometimes weighs 50lbs. per bushel. It is, however, very liable to be shed by the wind after it begins to ripen; it requires a fine dry tith.

5126. The Friesland or Dutch oat, has plump, thin-skinned, white grains, mostly double, and the large one sometimes awned. It has longer straw than the Poland, but in other respects resembles it.

5127. The potato oat has large, plump, rather thick-skinned, white grains, double and treble, with longer straw than either of the last two sorts. It is almost the only oat now raised on land in a good state of cultivation in the north of England and south of Scotland, and usually brings any other variety. It was discovered growing in a field of potatoes in Cumberland, in 1788; and from the produce of the single stalk which there sprung up by accident, probably from the manure, has been produced the stock now in general cultivation.

5128. The Georgian oat, is a large, grained, remarkably prolific variety introduced from Georgia, by R. Barclay, Esq., of Bury Hill, to Britain and the north of Europe. On rich soil in good tith, Mr. Barclay finds it yield more grain per acre than the potato oat or any variety whatever.

5129. The Siberian or Tatarian oat (b), is considered by many as a distinct species. The grains are black or brown, thin and small, and turned mostly to one side of the panicle; and the straw is coarse and reedy. It is little cultivated in England, but found very suitable for the poor soils and exposed situations on the sides of the Dublin and Wicklow hills.

5130. A variety called the winter oat, Avene d'hiver, Fr., has lately come into notice in some parts of England, but we have not been able to ascertain its origin. Mr. Bennett of Chaxhill, near Gloucester, sows two bushels per acre in October; finds the plants very luxuriant at Christmas, tillering like wheat: he depastures them with ewes and lambs; all the spring, and then cuts them up, and reaps an ample crop early in August. The grain is rather longer than that of the white oat, and the colour rather lighter than that of the black oat; Mr. Bennett received the seed from a friend in Monmouthshire, who he conjectures received it from Bristol, so that it is probably a recent importation. (Country Times, Feb. 8th, and Cor. with Mr. Bennett.)

5131. There are other varieties, as Church’s oat, the Angus oat, the dun oat, &c., but they are either too local or obsolete to require particular notice. In the oat, as in other plants extensively cultivated, new varieties will always be taking the place of old ones.

5132. To procure new varieties adopt the mode by selection, by which, as it appears above, the potato and red oat were brought forward; or proceed systematically by cross impregnation, as directed for raising new varieties of wheat. Degeneracy, Brown
observes, has taken place to a certain extent in the potato oat; but it is presumed that the consequences might be removed with ease, were first principles returned to. To make a selection of the strongest ears, which carried the purest grain, is not a difficult business; and were this selection attended to by half a dozen farmers in a district, it is obvious, that the breed, or variety, might be preserved pure and uncontaminated. If slovenly farmers were not provided with good seed, it would be their own fault; since, if they would not take the trouble to select and breed for their own use, they might always be provided by those who were either better qualified for making the selection, or were more attentive to the interests of agriculture. (Brown.) Some of the Northumbrian farmers have been at the pains to select the grains, instead of the ears, after being threshed. The best seeds are picked out by hand by women.

5153. In choosing a sort from among the varieties described, the potato and Poland are the best for lowlands, and the red oat for uplands and late climates in a state of good cultivation. For inferior soils the white or common oat, and for the poorest of all the black oat, may be adopted.

5154. The soil for oats may be any kind whatever, from the stiffest clays to moss or bog, provided it be laid sufficiently dry. The most tenacious clays, and meagre gravels and sands, where scarcely any useful seed-bearing plant, except buck-wheat, could be grown, will produce a crop of oats if ploughed at a proper season, and the seed judiciously sown and covered.

5155. The preparation of the soil for oats is less than for any other grain. It is almost always the first crop on newly broke-up lands; and as it prospers best on a soil not too finely pulverised, it is commonly sown on one earth. In regular rotations, oats are chiefly sown after grass; sometimes upon land not rich enough for wheat, that had been previously summer-fallowed, or had carried turnips; after barley, and rarely after wheat, unless cross-cropping, from particular circumstances, becomes a necessary evil. One ploughing is generally given to the grass-lands, usually in the month of January, so that the benefit of frost may be gained, and the land sufficiently mellowed for receiving the harrow. In some cases a spring furrow is given when oats succeed wheat or barley, especially when grass-seeds are to accompany the crop. The best oats, both in quantity and quality, are always those which succeed grass; indeed, no kind of grain seems better qualified by nature for foraging upon grass-land than oats; as a full crop is usually obtained in the first instance, and the land left in good order for succeeding ones. (Tr. on Rural Affairs.)

5156. The climate for oats should be cool and moist; when dry and warm, the panicles are so dried and contracted that they cease to convey sufficient nourishment to the ears, which thus never become plump, but thick husked, long awned, and unproductive in meal. This is very often the case with the oats in Scotland in a very dry year, and very common in the south of England in most years.

5157. The season of sowing oats is from the last week in February to the end of April. About the middle of March is preferred by the best farmers. No preparation is ever given to the seed; but it should be plump, fresh, and free from the seeds of weeds. Common oats sown in autumn are generally killed during winter, the plant being in this respect more tender than wheat, rye, or barley bigg. In some parts of Ireland, and especially in the county of Dublin, the Friezland oat is sown in autumn; and the advantage is they ripen nearly a month sooner than those sown in spring, an important object in a moist climate.

5158. The quantity of seed, where oats are sown broad-cast, is usually from four to six bushels to the acre. Land sown with potato oats requires less seed, in point of measure, than when any of the other sorts is used: first, because this variety fillers better than any other; and next, because having no awn, a greater number of grains are contained in a bushel.

5159. The mode of sowing oats is almost universally broad-cast; but where they are sown after turnips, or on other well pulverised soils, some adopt the row culture.

5160. The after-culture depends on the mode of sowing, but seldom consists of more than weeding before the flower-stalks begin to shoot up.

5161. In harvesting oats in England, they are generally cut down with the scythe, and carried loose to the barn or stack; but in the northern districts, and where threshing machines are used, whether mown, or, what is most usual, reaped with the sickle, they are tied in sheaves to facilitate the process of threshing. Oats are ready for the scythe or sickle when the grain becomes hard, and the straw yellowish. They should generally be cut before they are dead ripe, to prevent the shedding of the grain, and to increase the value of the straw as fodder. They rarely get much damage when under the harvest process, except from high winds, or from shedding, when opened out after being thoroughly wetted. The early varieties are much more liable to these losses than the late ones; because the grain parts more easily from the straw,—an evil to which the best of grain is at all times subject. Early oats, however, may be cut a little before
dead ripe, which, to a certain extent, lessens the danger to which they are exposed from high winds; and if the sheaves are made small, the danger from shedding after rains is considerably lessened, because they are thus sooner ready for the stack. Under every management, however, a greater quantity of early oats will be lost during the harvest process than of the late ones; because the latter adhere firmly to the straw, and consequently do not drop so easily as the former. (Brown.) In harvesting oats in wet seasons, the practice of gaiting the sheaves (3176.) is generally adopted. In Sweden, in most seasons, the oat crop is dried on frames or poles (704.); and in Russia, not only oats, but barley and rye, are kiln-dried in the straw.

5142. Kiln-drying oats and other corns in the straw has been found necessary, and is very generally practised through the north of Russia, Livonia, Courland, and Lithuania, being the last operation of harvest for preserving all kinds of corns, peas, beans, and buck-wheat. They are dried in the fields as much as can be; but, when brought home, they are kiln-dried, and are then ready to be either threshed out immediately, or put up in barns, without any danger of either corn or straw becoming musty or rotting. The common practice of the boors is, during winter, to thresh out by degrees, as in this country, their oats and barley, in order to have straw fresh for their cattle, such straw being their only provender. The process of kiln-drying by no means prevents the germination of the grain when used for seed, while it not only preserves the grain and straw but improves their taste and calibarity. It enables Russia to export large quantities of rye and wheat, with less risk of damage to the grain than is incurred by other nations of the north of Europe.

5143. The kiln (fig. 728.) in general and established use throughout Russia, for the purpose of drying corn in the straw, is heated commonly by fires of wood. It is a simple and cheaply erected structure, the walls eight feet high, and fifteen feet square within. At this height there are two strong cross-beams (a), to support the small timbers, laid over them as ribs. The corn stands in sheaves above these ribs (b), closely set up, the land ends of the sheaves down, and the corn or grain ends up; the walls then rise above the ribs about five or six feet more, the kiln being closed by a simple ceiling of cross joints at this height, covered with thin turf. Any cheap and ordinary roof answers to cover the whole. The fire-place is constructed so as to throw back the ascending spark; a small porch (c), directly opposite to the fire-place, prevents violent blasts of wind, and covers from rain the fuel and the attendant. About 300 sheaves (twenty-five stocks) of corn are dried at one time. It is put on in the evening, and left on the kiln through the night, after the wood has been burned into charcoal, and the door above the fire-place closed. At one end of the kiln there is frequently an open shed or barn (d), for convenience in bringing corn to, or taking it from, the kiln.

5144. The produce of oats is generally considered greater and of better quality in the northern than in the southern counties; and the reasons are obviously that, in the former, more attention is paid to their culture, and the climate is more favourable for the maturation of the grain. Ten quarters an acre is reckoned a good crop in the north, but the produce is often twelve and thirteen quarters, and the straw from two to three and a half loads per acre.

5145. The produce of oats in meal amounts to 8lbs. for 14 lbs. of corn. Sir H. Davy found 103 parts of oats afford 59 parts of starch, six of gluten, and two of saccharine matter.

5146. The use of oats in the north, in Ireland, and in some parts of Yorkshire and Derbyshire, is partly for meal and partly for horse-food. In the south it is almost entirely for horse-food, poultry, and grouts for gruel. It is occasionally malted and used in distillation. The fine powder which is produced by husking the corn, or making grist, forms the sovens of the Scotch (the flummery of the Irish), an agreeable light and wholesome supper dish.

5147. The diseases of the oat are few. Sometimes it is found attacked by the smut; but the more common injury sustained by oats is from wire-worms, or larvae of insects which generally abound in lands newly broken-up from turf. One of the most certain modes of avoiding these is, by not ploughing the ground, especially if old turf, till immediately before sowing. By this means the insect is turned down, and before it can work its way to the surface (if ever it does) the corn is beyond its reach. In this way gardeners destroy and retard the progress of the gooseberry caterpillar by digging under the bushes; for it is found that the eggs and larvae of insects, like seeds and bulbs, when buried too deep in the ground, have their progress retarded, or their vital principle destroyed. In late harvests, more especially in the northern parts of the island, the oat is liable to be frosted and rendered unfit for seed before being harvested. There is no remedy for such an accident; but we have shown (4997.) how it may be detected, so as not to disappoint the sower of such grain. (Encyc. of Gard. 4663.)

Sect. V. Cereal Grasses cultivated in Europe, some of which might be tried in Britain.

5148. The cereal grasses which the climate of Britain does not readily admit of cultivating, are the maize, Canary corn, millet, and rice.
SUBSECT. 1. *Maize, or Indian Corn.* — *Zea Mays* L.; *Monocro Triandra* L., and *Granisce* J. *Le Mais, or Blé de Turquie,* Fr.; *der Moys, Germ.; Gran turco,* Ital.; and *Maiz,* Span.

5149. *The maize* is the noblest looking of the cereal grasses. It is considered to be a native of South America, to have been cultivated in Mexico and Peru from time immemorial, to have been introduced to Europe about the beginning of the 16th century, and to England in 1562. It is at present cultivated in almost every part of the universe where the summer temperature equals or exceeds that common to latitude 45°, and even to 48°. In France, in Arthur Young's time (1787), the principal country of the maize was to the south of a line drawn from Bordeaux to Strasbourg, in lat. 48° 37'; but it is at present cultivated as far north as Nancy, which is in latitude 49° — a fact which shows that this grain is taking a wider range of temperature. "It flourishes on the western continent from about the 40th degree of southern to higher than the 45th degree of northern latitude. It is extensively produced in Africa and in Asia; on all the shores of the Mediterranean, in Spain, Italy, part of France, and the countries of the Levant, it is the food in most common use. Of the cultivated Cerealia, indeed, it is that which, next to the rice, supplies food to the greatest number of the human race; and it may be held to be the most valuable gift of the new world to the old." (Quar. Jour. Ag. i. 482.) In England it has been cultivated for upwards of a century, in nursery gardens in the neighbourhood of the metropolis, for the curious purpose of supplying seedsmen in all parts of the island with ears of the corn to ornament their shop windows; it has also been grown in the kitchen gardens of some individuals who have lived in America, for the purpose of using the ears in a green state: it has been tried also in the fields, and more especially in 1828 and 1829, in consequence of the public attention being called to the subject by Mr. Cobbett.

5150. *As a bread corn* it cannot be greatly commended; the ear is highly productive of flour, but that flour is deficient in gluten, and cannot be made into bread without the addition of a large admixture of the flour of wheat. For fattening cattle and poultry of every description it is found excellent, and its culture in Europe can only be recommended with a view to this object.

5151. *Varieties.* Like other plants which have been long in cultivation in various countries, there are numerous varieties of the maize. According to Lagenauer, there are 30 varieties known in Spain. That grown in the warmer parts of America is called the large yellow, *Mais jaune grand* Fr. (fig. 729). There is a large red, which differs from the other only in the colour of the skin of the grain; both have very large and hard some ears (fig. 730). There is the large yellow Bint, the large white flint, the sweet corn, the pearl corn, the maize quarantine, ripening in forty days, and the Egyptian or chicken corn, *Mais a pointe,* le plus petit et le plus précoces, of Villmorin's catalogue. There is also what is called Cobbett's corn (fig. 731), which seems to be nothing more than the Mais quarantine. The two last varieties have small handsome ears (figs. 722 and 732), and can hardly be distinguished from each other. All these sorts have been tried together in the same field, and the Egyptian or chicken corn found decidedly the most early, and the Maize quarantine, forty days' corn, or Cobbett's corn, next. These two sorts, therefore, alone deserve culture in this country. The *Zea Coronata,* the Valparaiso corn, is a distinct species, to which a sort of religious reputation is attached, on account of the grains, when roasted, splitting regularly into the form of a cross.
5154. The preparation of the soil may be the same as for a crop of barley, according to Cobbett; but we should say, the same as for a crop of turnips on the raised ridgetop or Northumbrian system, although the corn on such plants will be much less likely to ripen than that produced on a dry, warm, sandy, or calcareous soil. It must be observed, from what has been before advanced, that there are few, if any, parts of the United States or New York where the climate will be at all suitable to this grain.

5155. Sowing. The quantity of seed required is from one bushel to three bushels per acre. In Long Island, near New York, the time of sowing is from the 10th to the 20th of May; in France, from the 15th of April to the 15th of May; in England, from the 15th of April to the 20th of May. When this is done, we doubt that, in situations where the earliest varieties will succeed at all, they will succeed if sown a week or ten days later. The grain will retain its vegetative powers for at least six years. (Gard. Mag. vol. vi. p. 444.)

5156. The mode of planting the corn in America is by drawing shallow drills, commonly three or four feet distant from each other, and dropping the seeds by hand, at eight inches apart, in the row. This distance is evidently too great for the early dwarf varieties; and we think three furrows, or twenty-seven inches, the ordinary width between rows of potatoes and turnips, much more suitable. We should decidedly prefer dibbling, either by hand or by a machine, to opening a drill and depositing the seeds. In several places in France the seeds are sown broad-cast and harrowed in, and the after-culture consists in hand-hoeing between them. By sowing on raised drills the horse-hoeing system may be applied as effectually as in the culture of turnips or beans. Cobbett recommends intervals of one foot between the rows of five feet, and the plants at six inches distance in the row, with a view to admit a superior degree of tillage between, with a view to the wheat crop. He also describes the mode of planting in hills. The situations of these hills having been marked out by a light plough, or even by trampling a log of wood, first in lines five feet apart in one direction, and next in lines in the opposite direction at right angles to the former, so as to leave the surface in squares, the planter takes a hoe, and at every intersection of the lines makes a little hole about an inch and a half deep, and about six inches in diameter, and in this hole five or six seeds are regularly distributed, and covered over with fine earth to the depth of an inch and a half. It is evident that by this mode of planting the ground may be very thoroughly worked during the growth of the crop; but it is evident also that it could only be adopted in this country on dry soils, that would admit of being kept during spring and autumn without water furrows.

5157. Transplanting maize may be adopted on a small scale, the advantages of which are that the ground may be better prepared before planting, and that the crop may be made to come in in succession with one which has stood in the ground during winter. The plants may be raised in a hotbed, and protected by sods or they may be raised in a warm border of soil, covered with straw or straw mats during nights till the common ash, the mulberry, or the walnut are in leaf: they may then be carefully raised and transferred to the field, with a small portion of earth attached to each, planted with a spade or trowel, and watered unless it should happen to rain.

5158. The after culture, according to Cobbett, commences with sowing away birds and destroying slugs, and afterwards in removing weeds and stirring the soil. The plants will be one foot and a half high in July; and no one at that season, Cobbett says, need be afraid of leaning the roots with the plough as much as he will. One thing is certain, he says, that if the weather be fine, and both of the rows be not ploughed at all, there will be no crop at all. The last process with the plough is earthing up, which is said to be useful for two purposes: first, to keep the plants steady, in case of very rough winds; and, second, to give it a fresh stock of roots. "Leave a corn-plant with nothing but a little earthing up, and without earthing up, and you will see all around its roots coming out just above the ground, and going immediately down into the ground."

5159. Topping the plants. The male and female blossoms being on different parts of the plant, have given rise to this operation. The male flowers are always situated on the top or summit of the stem, and the female flowers below, near the bottom. "The flowers at the top having performed their function, and deposited the pollen on the stigma beneath, become no longer necessary to the plant; and they, accordingly, with all the elevated part of the stem which supports them, may be wholly removed. This process is termed topping by the Americans, and is delayed until the blades or leaves may be also stripped.
MAIZE, but and but it upon the pressure grains of the ears, rats, chestnuts, Europe, and the poorest feeding, winter, and the inhabitants of the Neapolitan territory live chiefly on maize; as those of some mountainous districts in the north of Italy live on bread made from chestnuts, or buckwheat. The most important purpose to which the corn unsheathed is used in Europe, appears to be like that noted for their larvae, that until the next summer of France and south-east of Germany; and the small poorer in these countries are also chiefly fed on in America and Australia, and the smallest poultries in these countries are fed with maize, the grains; and the next poultries in these countries are fed with maize, the grains

**5164. Turkey feeding,** according to Cobbett, is one of the most important poultries. If the farmer shall have not more than three or four turkeys, he may try:—*We killed, last spring, one single pullet, not of a large breed, out of which we took some fat weighing three-quarters of an ounce.* We fattened most perfectly and most finely ten turkeys in the same manner; and as to geese and ducks, which fatten easier than either of the former, they will get fat in this manner in a short space of time. If you wish to have fresh eggs in winter, you need resort to no stripping of barly in bez or in wine, or to giving the hens hampsted, or the seed of nettle, as Frome, &c.; nor must such a feat as keeping the hen warm; give them plenty of corn, while, and you will have fresh eggs all the winter long. To the very little child, as very and very tender turkeys, may be killed, but there you too take it down whole; and, large as it is, the sparrows will eat it as fast as the fowls; and, if you be much inclined with them, and do not wish to have a numerous and early born of them next spring, you must feed the poultry close to the door, or stand by them during the meal, which, however, is an accident to the farmer and the stock is great so that their claws are filled in one minute. It is very well known that, in order to have a fat turkey, or even a really fat fowl, we are compelled to cram them by a certain process. If the farmer has down of these, there she sits (for she can trust nobody else to do it), with a small damper over her, and rather upon her, with a milk of barley-meal rolled into an oblong form, and with a bowl of warm milk, or with some gruel; or one little turkey can be kept at her own stirrup; the farmer, means open with her left hand, putting in the food with his, and dried; they are then put into an oven, and kept in a moderate oven for a week, and then put into a dry place, and kept there, and this, and then put into the oven, every day now and then pouring down a mixture of the meal upon the top of the meal, and upon the little victuals deserve good rank. There she sits, if she has two dozen of them, to get them well killed, two good hours. Sometimes they reject the food, and fluster about, and show the will, and this is a common and agreeable thing, and such is the case; it takes up a great deal of time, and yet these things cannot be made sufficiently fit without this operation, in which, I dare say, 30,000, and ate at this very moment (eight o'clock in the morning) engaged, in the counties of Norfolk and Suffolk. If all these women could be brought together, and were to hear me say

sorts can be grown; is considerable; but in this country, where only the dwarfs sorts could be cultivated with success, it would not equal that of a crop of oats or barley. 5165. The application of this crop, according to Cobbett, is various and important; "pig feeding, sheep feeding, or for their horses and oxen in spring; they are given to race horses and other delicate and highly prized animals. They are cut into chaff, and then mixed with barley and rye. Mr. Cobbett has stated this part of the produce to be more valuable than a crop of hay; but he has not given us data, either as regards the weight of the crop, or the quantity of the amount, to enable us to judge the correctness of his opinion. In France and southern Europe, these parts of the plant are, in like manner, used for fodder; but we are not aware that they are held in any thing like such high estimation as a crop of hay is with us.* (Treatise on Agriculture, vol. 6, p. 214, and Quar. Journ. Agr., May, 1829, p. 734.)

5061. Shelling or threshing. This, Cobbett tells us, is done in America by scraping or rasping the ears upon a piece of iron, fixed across a tub, into which the grains fall. The iron is commonly a bayonet. In this country there are machines of different kinds (Agr. vol. 734, and 502.) which perform the operation of shelling with great rapidity; but whoever has a threshing machine might, by setting the rollers and some wanton, than usual, dispense with manual labour, both in the operations of husking and shelling; and indeed we see no reason why the crop should not be harvested by the combined labour of orchard and hay-stacks, with Gladsome's bean reaper (2740), and sheaved, shaken, stacked, and threshed, like any other grain.

5162. Produce. In America and Australia, the produce in corn is from fifty to seventy bushels to the acre; on the continent it is generally between fifty and sixty; and the produce in this country it appears by some of the best accounts recorded in the Gard. Mag. vol. vi. p. 60 to 61, would probably be similar, notwithstanding the circumstance of Mr. Cobbett, Mr. Moore of Sandy, in Bedfordshire, and some others, having raised on small spots at the rate of 100 bushels per acre and upwards. The produce in straw in America and Australia, in warm countries, where it is cut, is not more than half that of one in Europe, and the Merchants' List of 1829, and vol. 101, p. 618.
and prose, that I could save them all this trouble, they would saw; food loses you, sir; you are the bee's inventor of
text and sugar excepted) that ever administered to the comfort of
unnecessary! Well, then, I do for them now; let their
husbands raise some Coddett's corn, the heathen spouts may be
converted into sputterandles for them, the warm milk or
greaty water may be given to young pigs, the bowl may be
converted into a poring-genner a boy to eat porridge out of, the
corpse, who are up to eat, and the ree, and the four hours saved morning and evening may be
employed in spinning and preparing the stuff to make
him shift, and dress, or, which makes less noise, in knitting
stockings for the whole family." (Quar. Jour. Agr. vol. I.
5165. In common with other grain, maize may be fermented, so as to produce beer; or distilled from, so
as to produce spirits; the straw containing a good deal of saccharine matter which might also be
extracted.
5166. The green ears of maize are applied to various purposes. In the neighbourhood of Paris, before
the male blossom has expanded, the female is gathered and pickled, in the manner of cucumbers; and this is
practised to some extent by the French and Germans. When the grain has arrived at its milky state, the
ears are then gathered for the purpose of boiling or roasting. In America they are toasted on or before
hot embers, and eaten with salt and butter. Boiled, they are not quite so delicate; but are still very
good, especially if boiled with fat pork. The ears are generally fit for these purposes during the month of
September, and a large field may afford soft ears for six weeks afterwards.
5167. The meal of maize, besides being given to the smaller poultry, is also used for fattening swine, old
sheep which have lost part of their teeth, and for feeding old horses which cannot grind the ears whole.
Of a finer quality it is given to negroes, and eaten by various persons in America, in the form of porridge,
puddings, and cakes. In this country, the Rev. Henry Berry of Pensham House, Worcestershire, has
found maize meal, purchased from Liverpool, superior to oatmeal in maintaining the condition of his
hounds. (Country Times, March 25th, 1830.) The meal of maize, made into paste, and fried with fat
bacon, is the ordinary food of the peasantry of great part of the Brabant. It serves them likewise for feeding
their fowl, of which they feed great quantities for the markets of the rest of Brabant and of Holland. (Comm.
Board of Agr.)
5168. Diseases and enemies. The Phæn'ma forficulis Lin. is said to deposit its eggs in the stems of the plant,
and the larvae which these produce eat out its interior, so as to weaken the strength of the spikes. There
are also three species of smut, Ucello Pers., which are parasitic on the maize, and destroy the grain by reducing it to a black powder. One species is peculiar to the flower, attacks it before it arrives at
maize, and leaves it in a state of black powder. The French writers recommend washing and pickling in the
same manner as for wheat. The stalks and leaves, being very sweet, are greedily sought by field rats, mice, and other enemies. In the granary, the maize, like other grains, is attacked by
different species of weevil, this insect produces serious injury in America, but is not very likely to be troublesome in this country.

Subsect. 2. Canary Corn. — Phalaris canariensis L.; Triandra Digitata L., and Gra
mineae J. Alpiste de Canaire, Fr.; Kanariengras, Ger.; Palari, It.; and Alpheas,
Span. (fig. 785.)

5169. The Canary grass is an annual, with a culm from a foot to eighteen inches in
height, and lively green leaves almost half an inch in width. The seeds are thickly
set in a subovate panicle or spike. It is a native of the Canary Islands; but now
naturalised in several parts of England, and on the Continent. It flowers from June to
August, and ripens its seeds from September to October. It has
long been cultivated in the Isle of Thanet, and a few other places in
Kent and Essex; it is there considered an uncertain crop, both
on account of the seasons, it being the latest of all the grasses in
ripening its seeds, and of the fluctuation of prices.
5170. The culture of the Canary grass consists in pulverising a
loumny soil in good heart, or manuring it if worn out; though every
judicious farmer tries to avoid giving manure to a corn crop unless
after a naked fallow. The seeds are sown in rows at about a foot
apart, generally by the ribbing process: the season the month of
February, and the quantity of seed four or five gallons per acre.
The after-culture consists in repeated hoeings and weedicings.
5171. The roasting process seldom commences before the end of
September. The culm being leafy, and the seed difficult to separate
from the chaff; it requires to lie in handfuls for a week or more, and to
remain more than that time in the field after being tied up in sheaves.
In the Isle of Thanet it is cut with a hook, provisionally called a
twib and a hink; by which it is laid in heaps, or wads, of about a
sheaf each. The seed clings remarkably to the hink; and, in order to
detach it, the crop is left a long time on the ground, to receive
moisture sufficient to loosen the enveloping chaff; otherwise it would
be hardly possible to thresh out the seed. The wads are turned from
time to time, to have the full benefit of the rains and sun.
5172. The common produce of Canary grass is from thirty to
thirty-four bushels per acre; but under the best management in the
Isle of Thanet it is often fifty bushels per acre.
5173. The use of the seed is chiefly as food for Canary and other cage and avairy birds.
The chaff is superior to that of every other culmination of plant for horse-food, and the straw,
though short, is also very nutritive.

Subsect. 3. The Millets. — Pannicum and Sorghum L.; Triandra Digitata and Poly
gramia Monocia L. and Gramineae J. Panis and Sorgho, Fr.; Panick and Hirse,
Ger.; Panico and Sago or Sorgo, It.; and Alconida, Span.
5174. Of the millet there are three distinct genera: the Polish millet (Digitaria), cultivated
in Poland; the common millet (Pannicum), or panic grass, cultivated in Germany,
and sometimes in this country; and the great or Indian millet (Hóleus), cultivated in India, Italy, and America.

5175. Of the common millet there are three species; Setária germanica (fig. 736, a), a native of the south of Europe; the P. milliaceum (b), a native of the East Indies; and the Setária italica (c), also of Indian origin.

5176. The German millet (Moéa de Hongrie, Fr.; S. germanica, a) rises with a jointed reed-like stalk, about three feet high, and about the size of the common reed, with a leaf at each joint a foot and a half long, and about an inch broad at the base where broadest, ending in an acute point, rough to the touch, embracing the stalk at the base, and turning downwards about half the length. The stalks are terminated by compact spikes, about the thickness of a man's finger at the bottom, growing taper towards the top, eight or nine inches long, and closely set with small roundish grain. It is annual, and perishes soon after the seeds are ripe. There are three varieties of it, which, though similar, were different. It was formerly cultivated for bread in some of the northern countries.

5177. The Italian or cultivated millet (Millet commun, Fr.; Panicum milliaceum, b) rises with a reed-like channelled stalk, from three to four feet high; at every joint there is one reed-like leaf, joined on to the stalk, which is clothed with soft hairs; the leaf has none, but has several small longitudinal furrows running parallel to the midrib. The stalk is terminated by a large loose panicle hanging on one side. Of this species there are two varieties, the brown or yellow kind of which was formerly in cultivation, and is now sometimes sown for feeding poultry, and as a substitute for rice.

5178. The Italian millet (Pani's of Italie; Millet à grappe, c; Setária Italiaca, d) rises with a reed-like stalk, nearly four feet high, and much thicker than that of the preceding; the leaves are also broader. The spikes are a foot long, and twice the thickness of those of the common millet, but not so compact, being composed of several roundish clustered spikes; the grain is also larger. There are two or three varieties of this, differing only in the colour of the grain. It is frequently cultivated in Italy (whence its trivial name), and other warm countries. It is a native of both Indies, and of Cochín China.

5179. The Polish millet, or manna grass of the Germans (Digitária sanguinalis, formerly Panicum sanguinalis, fig. 737), is a low decument, annual plant, seldom rising above nine inches or a foot high, with hairy leaves and slender panicles. It tolerates much, and forms a good tuft, and rooting at the joints. It is a native of England but not common. It grows in abundance in Poland, and is sometimes cultivated, the seeds being used like those of the other millets as a substitute for rice or sago.

5180. The great or Indian millet (Hóleus Sógóna, L., Sógóna vulgaris, W. c, A, fig. 738. Sórghum, gros grain d'Italie, Fr.; Sargassum, Ger., Sargina, Ital.; and Móloa, Span.) has a stem which rises five or six feet high, is strong, reedy, and like those of the maize, but smaller. The leaves are long and broad, having a deep furrow through the centre, where the midrib is depressed in the upper surface, and is very prominent below. The leaves are two feet and a half long, and two inches broad in the middle, embracing the stalks with their base. The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey wheat; these are succeeded by large roundish seeds, which are wrapped round with the chaff. This grain is a native of India, where it is much used to feed poultry, and is frequently sent to Europe for the same purpose. It is much cultivated in Arabia, and most parts of Asia Minor; and has been introduced into Italy, Spain, Switzerland, and some parts of Germany, also into China, Cochín China, and the West Indies, where it grows commonly five or six feet high, or more, and being esteemed a hearty food for labourers, is called negro Guinea corn. Its long ears or bristles defend it from the birds. In England, the autumns are seldom dry and warm enough to ripen the seed well in the field. In Arabia it is called dora or orraya; the flour is very white, and they make good bread of it, or rather cakes, about two inches in thickness. The bread which they make of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons, sometimes for swine, kine, and horses. Carasalpinus says, that cattle fed on the green herb are apt to swell and die, but thrive on it when dried. They make brushes and brooms of its stalks in Italy, which Ray observed in the shops at Venice, and which are sent to this country. Of this species there are two distinct varieties; one distinguished by black, and the other by red, husked seeds, besides subvarieties.

5181. The only sorts of millet which can be cultivated with success in this country are the German, cultivated, and the Polish sorts. According to Professor Thaer, the cultivated is to be preferred, as having the largest grain.

5182. The soil for the millet should be warm, sandy, rich, and well pulverised to a good depth. The seed is sown in May, very thin, and not deeply covered. In the course of its growth no plant, Professor Thaer observes, is more improved by stirring the soil, after which it grows astonishingly fast, and smothers all weeds.

5185. In harvesting the millet, great care is requisite not to shed the seed; and as it ripens rather unequally, it would be an advantage to cut off the spikes as they ripen, as
in reaping maize. No grain is easier to thresh, or to free from its husk by the mill. It is used instead of rice, and in Germany bears about the same price. It produces a great bulk of straw, which is much esteemed as fodder.

5184. The great Indian millet will grow in this country to the height of five or six feet; but will not ripen its seeds, or even flower, if the season is not dry and warm. If its culture is attempted, it should be raised in a hothed and transplanted

**Subsect. 4. Rice, and some other Cereal Grámina.**

5185. The rice (Oryza sativa, fig. 739.) has been tried in this country, and, if sown very early, would probably ripen its seeds. The hill variety, which does not require watering, would probably succeed best. But there is no inducement to cultivate this and other grains or seeds when they can be imported at so low a rate. We merely introduce them to record the resources of British agriculture in case of necessity.

5186. The Zizânia aquática (fig. 740.) might be cultivated on the margin of ponds for its seeds, which much resemble those of Polish millet. It is exceedingly prolific, grows in great luxuriance, and produces abundance of bland farinaceous seeds, in all the shallow streams of the dreary wilderness in north-west America, between the Canadian lakes and the hilly range which divides Canada from the country on the Northern Pacific Ocean. Its seeds contribute essentially to the support of the wandering tribes of Indians, and feed immense flocks of wild swans, geese, and other water fowl, which resort there for the purpose of breeding. Productive as is this excellent plant, and habituated to an ungenial climate, and to situations which refuse all culture, it is surprising, says Pinkerton (Geog. vol. iii. p. 330.), that the European settlers in the more northern parts of America have as yet taken no pains to cultivate and improve a vegetable production which seems intended by nature to become, at some future period, the bread corn of the north.

5187. The Glycérâ flóâtans resembles the Zizânia, and the seeds are used in Germany like those of Polish millet. Various species of Pánicum, Hórdem, and Brónus afford tolerable supplies of edible seeds.

5188. The buck-wheat (Polýgonum Fagópyrum; Rîz, Fr.; Reiss, Ger.; Riso, Ital.; Arròs, Span.) is vulgarly considered as a grain; but not being a bread-corn grass, we have classed it among manufactory plants. (Chap. VIII. Sect. IV.)

---

**Part III.**

**Chap. III.**

**Culture of Leguminous Field-Plants, the Seeds of which are used as Food for Man or Cattle.**

5189. The seeds of the cultivated legumes are considered to be the most nutritive of vegetable substances grown in temperate climates. They contain a large proportion of matter analogous to animal substances, having when dry the appearance of glue, and being as nourishing as gluten. To the healthy workman this substance supplies the place of animal food; and Von Thaer states, that in Germany neither sailors nor land labourers are content unless they receive a meal of legumes at least twice a week. The straw or haulm, he says, cut before it is dead ripe, is more nourishing than that of any of the cereal grasses. But leguminous plants are not only more than all others nourishing to man and animals, but even to vegetables they may be said to supply food; since they are not only known to be less exhausting to the soil than most other plants, but some of them, and more especially the lupine, have been ploughed in green as manure from the earliest times. Many scientific agriculturists consider a luxuriant crop of peas or tares as nourishing the soil by stagnating carbonic acid gas on its surface; which corresponds with the universal opinion of their being equal to a fallow, and with the value set on them in rotation, as already explained. (1939.) Two reasons may be given for the circumstance of peas and tares not exhausting the land so much as other crops: first, because they form a complete shade for the ground; and next, because they drop so many of the
leaves upon the surface. The legumes cultivated in British farming are, the pea, bean, tare, and vetch, to which might be added the lentil, kidneybean, and chick pea.

5190. The nutritive products of these plants are thus given by Sir H. Davy, Einhoff, and Thaer:—

5191. The pea is the most esteemed legume in field cultivation, both for its seed and haum. It is supposed to be a native of the south of Europe, and was cultivated by the Greeks and Romans. In this country it has been grown from time immemorial: but its culture appears to have diminished since the more general introduction of herbage, plants, and roots; and the pea, except near large towns for gathering green, and in a few places for boiling, has given way to the bean, or to a mixture of peas and beans. There are various inducements, however, to the cultivation of peas in dry warm soils near large towns. When the crop is good and gathered green, few pay better: the payment is always in cash, and comes into the pocket of the farmer in time to meet the exigencies of the hay, and sometimes even of the corn, harvest. The ground, after the peas have been removed, is readily prepared for turnips, which also pay well as a retail crop near towns; and the haum is good fodder.

5192. The varieties of the pea are numerous; but they may be divided into two classes: those grown for the ripened seed, and those grown for gathering in a green state. The culture of the latter is chiefly near large towns, and may be considered as in part belonging to gardening rather than agriculture. There has lately a new sort of pea been brought into notice about Banbury in Oxfordshire. It is called the “nimble hog pea.” It appears to be a grey variety of the early frame, as it has single flowers, and is fit to cut about the end of June, notwithstanding it must not be sown earlier than the middle of April. On the excellent land about Banbury the produce is four quarters to the acre, and turnips sowed on the stubble are up and sometimes hoed out before the regular turnip crop!

5193. The grey varieties (*Pisum gravis*, *Pis-agrum*, *Bisette*, Fr.) are, the early grey, the late grey, and the purple grey; to which some add the Marborough grey, and horn grey.

5194. The white varieties (*Pis blanc*, Fr.) grown in fields are the pearl, early Charlton, golden hetspur, the common white or Suffolk, and other Suffolk varieties.

5195. New varieties of the pea are readily procured by selection or impregnation, of which a striking example given by Knight has been already referred to. (1632.)

5196. In the choice of sorts, where it is desired to grow grey peas for the sake of the seeds or corn, the early variety is to be preferred in late situations, and the late variety in early ones; but when it is intended to grow them chiefly for covering the ground and for the haum, then the late varieties claim the preference, and especially the purple grey. Of white peas, to be grown for gathering green, the Charlton is the earliest, and the pearl or common Suffolk the most prolific. When white peas are grown for boilers, that is for splitting, the pearl and Suffolk are also the best sorts.

5197. To have recourse to early sorts is supposed by some to be of considerable importance in the economy of a farm, when the nature of the soil is suitable, as by such means the crops may in many cases be cut and secured while there is leisure, before the commencement of the wheat harvest; and that where the nature of the soil is dry and warm, and the pea crop of a sufficiently forward kind, it may be easy to obtain a crop of turnips from the same land in the same year, as has been suggested above. But in this view it is the best practice to put in the crops in the row method, and keep them perfectly clean by means of attentive hand and horse hoeing; as in that way the land will be in such a state of preparation for the turnips, as only to require a slight ploughing, which may be done as fast as the pea crop is removed, and the turnip seed may be drilled in as quickly as possible upon the newly turned up earth. In some particular districts a third crop is even put into the same land, the turnips being sold oil in the autumn, and coleworts substituted for the purpose of greens in the following spring. This, according to Middleton, is the practice in
some places in Middlesex. But it is obviously a method of cultivation that can only be attempted on the warm and fertile kinds of turnip soil, and where the pea crops are early; on the cold heavy and wet descriptions of land it is obviously impracticable, and wholly improper.

5198. The soil best suited for peas is a dry calcareous sand; it should be in good tilth, not too rich nor dugged along with the crop. In Norfolk and Suffolk peas are often sown on clever leys after one furrow, or after corn crops on two furrows, one given in autumn, and the other early in spring.

5199. The climate required by the pea is dry and not over warm, for which reason, as the seasons in this country are very often moist and sometimes exceedingly dry and hot in June and July, the pea is one of the most uncertain of field crops.

5200. The season of sowing must differ considerably according to the intentions of the cultivator.

5211. For planting early to be sold green, they should be sown at different times, from January to the end of March, beginning with the driest and most reduced sorts of land, and turned in this intention in some southern counties they are sown in the autumn. For the general crops from February to April, as soon as the lands can be brought into proper order, is the proper season; the grey sorts being employed in the early sowings, and the white in the latter. Later than this the crop cannot be secured, in February, they should always be completed in the following month. It is observed by the same writer, that, in sowing after a single furrow, the white baking pea, of many sorts and under various names, is more tender than the grey and various kinds of hog peas; but he has many times put them into the ground in February, and, though very smart frosts followed, they received no injury. He has uniformly found, that the earlier they were sown the better. There is also a particular motive for being as early as possible. that is, to get them off in time for turnips. This is most profitable husbandry, and should never be neglected in dry and warm soils and situations. If they are sown in this month, and a right sort chosen, they will be more certain, so that turnips may follow at the season of sowing that crop.

5202. Steeping the seed in water is sometimes practised in late sowings.

5203. The quantity of seed must be different in different cases and circumstances, and according to the time and manner in which the crop is put into the ground; but, in general, it may be from two and a half to three bushels, the early sowings having the largest proportion of seed. In planting every furrow slice, Young says, two bushels and a half constitute the usual proportion; but, when drilled at greater distances, six or seven pecks will answer.

5204. The most common mode of sowing peas is broad-cast; but the advantages of the row culture in the case of a crop so early committed to the soil must be obvious.

5205. The best farmers always sow peas in drills either after the plough, the seed being deposited comminonly in every second or third furrow; or, if the land is in a pulverised state, by drawing drills with a machine or by rigging. In Norfolk and Suffolk peas are generally dilled on the back of the furrow, sometimes one and sometimes two rows on each; but dibbling in no manner appears to us so well suited for this purpose as the drill. In Kent, where immense quantities of peas are grown, both for gathering green and for selling ripe to the seedsmen, they are generally sown in rows from eighteen inches to three feet asunder, according to the kind, and well cultivated between. Peas laid a foot below the surface will vegetate; but the most approved depth is six inches in light soil, and four inches in clay soil, for which reason they ought to be sown under furrow when the ploughing is delayed till spring. Of all grain, beans excepted, they are the least in danger of being buried.

5206. The after culture given to peas is that of hoeing, either by hand or horse. Where the method of hand-culture prevails, it is the general custom to have recourse to two hoeings; the first when the plants are about two or three inches in height, and again just before the period in which they come into blossom. In this way the vigorous vegetation of the young crop is secured, and a fresh supply of nourishment afforded for the setting of the pods and the filling of the peas. At the latter of these operations the rows should be laid down, and the earth well placed up to them, the weeds being previously extirpated by hand labour. It has been stated, that in some parts of Kent, where this sort of crop is much grown, it is the practice, when the distance of the rows will permit, to prevent the vegetation of weeds, and forward the growth of pea crops, by occasionally horse-hoeing, and the use of the brake-harrow, the mould being laid up to the roots of the plants at the last operation by fixing a piece of wood to the harrow. This should, however, only be laid up on one side, the peas being always placed up to that which is the most fully exposed to the effects of the sun.

5207. In harvesting the ripened pea considerable care is requisite, both on account of the seed and haulm.

5208. When pea crops become ripe they wither and turn brown in the haulm and straw, and the pods begin to open. In this state they should be cut immediately, in order that the loss sustained by the peas may be as little as possible. It is observed that in the late or general crops, after they are reaped or rather cut up by means of a hook, it is the usual practice to put them up into small heaps, termed wads, which are formed by setting small parcels against each other, in order that they may be turned both in the soil and stem, and be kept from the weather. But, in the early crops, the haulm is hooked up into loose open heaps, which, as soon as they are perfectly dry, are removed from the ground and put into stacks for the feeding of animals, which are said to thrive nearly as well on it as on hay. When intended for horses, the best method would seem to be the cutting of them into chaff and mixed with their other food. Young says, that forward white peas will be fit to cut early in July; if the crop is very great they must be hooked; but if small, or only middling, mowing will be sufficient. The stalks and leaves of peas being very succulent, they should be taken up moist, and put in wet weather; for if they be cut dry, they become very liable to injury. White peas should always be perfectly dry before they are housed, or they will sell but indifferently; as the brightness and plumpness of the grain are considered more in them than in hog peas at market. The straw also, if well harvested, is very good fodder for all sorts of cattle and for sheep; but if it receives much wet, or if the heaps are not turned, it can be used only to litter the farmyard with. It is the practice in some districts to remove the haulm, as soon as it has been cut up by hooks constructed
with sharp edges for the purpose, to every fifth ridge, or even into an adjoining grass field, in order that it may be the better cured for use as cattle-food, and at the same time allow of the land being immediately prepared for the succeeding crop. When wet weather happens whilst the peas lie in wads, it occasions a considerable loss, many of them being shed in the field, and of those that remain a great part will be so considerably reduced in value. The crop of peas is of the greatest importance in peas together with the great uncertainty throughout their growth, and the frequently inadequate return in proportion to the length of hauin, has discouraged many farmers from sowing so large a portion of this pulse as other grain; so that on light lands which are in tolerable heart, the profit, in a good year, is far from inconceivable.

5209. In gathering green peas for the market, it is frequently a practice with the large cultivators of early green-pea crops in the neighbourhhood of London to dispose of them, by the acre, to inferior persons, who procure the podders; but the smaller farmers, for the most part, provide this description of people themselves, who generally apply at the proper season.

5210. The business of picking or podding the peas is usually performed by the labourers at a fixed price for the sack of four heaped bushels. The number of these labourers is generally in the proportion of about four to the acre, the labour proceeding on the Sundays as well as other days. It is sometimes the custom to pick the crops over twice, after which the rest are suffered to stand till they become ripe, for the purpose of seed. This, however, mostly arises from the want of pickers, as it is considered a loss, from the peas being less profitable in their ripe state than when green. Besides, they are often improper for the purpose of seed, as being the worst part of the crop. It is therefore better to have them clear picked when hands can be procured. After this they are loaded into carts, and sent off at suitable times, according to the distance of the situation, so as to be delivered to the salesmen in the different markets from about three to five o'clock in the morning. In many cases in other parts, the early gatherings are, however, sent to the markets in bulk bushel sacks, and are frequently disposed of at a high price of five shillings the sieve; but when by season they are used in the form of dried peas, stratified in large hampers, which contain about three bushels each, in the more early parts of the season, often fetch twelve or fourteen shillings the sack, but afterwards mostly decline considerably; in some seasons so much as scarce tenpence. This method of preserving the most profit in such pea seasons as are inclined to be cool, as under such circumstances the peas are most retarded in their maturation or ripening, and of course the markets kept from being overabundantly supplied.

5211. The threshing of peas requires less labour than that of any other crop. Where the hauin is to be preserved entire it is best done by hand; as the threshing machine is apt to reduce it to chaff. But where the fodder of peas is to be given immediately to horses on the spot, the breaking of it is no disadvantage.

5212. The produce of the pea in ripened seeds is supposed by some to be from three and a half to four quarters the acre; others, however, as Donaldson, imagine the average of any two crops together not more than about twelve bushels; and that on the whole, if the value of the produce be merely attended to, it may be considered as a less profitable crop than most others. But as a means of ameliorating and improving the soil at the same time, it is esteemed of great value.

5213. With respect to the produce In green peas in the husk, the average of the early crops in Middlesex is supposed to be from about twenty-five to thirty sacks the acre, which, selling at from eight to eighteen shillings the sack, afford about eighteen pounds the acre. The author of The Synopsis of Husbandry, however, states the produce about Dartford, in the county of Kent, at about forty sacks the acre, though, he says, fifty have sometimes been gathered from that space of land.

5214. The produce of peas in straw is very uncertain, depending so much on the sort and the season: in general it is much more bulky than that of the cereals grains; but may be compressed into very little room.

5215. The produce of peas in flour is as 3 to 2 of the bulk in grain, and husked and split for soups as 4 to 2. A thousand parts of pea flour afforded Sir H. Davy 574 parts of nutritive or soluble matter; viz. 501 of mucilaginous vegetable animal matter, 82 of sugar, 55 of gluten, and 16 of extract or matter rendered insoluble during the operation.

5216. The use of peas for soups, puddings, and other culinary purposes, is well known.

5217. In some places poordidge, brose, and bread are made of pea-flour, and rockened very wholesome and substantial. In Stirlingshire it is customary to give pea or bean biscuits to horses, as a refreshment, while in the yoke. The portion of peas not consumed as human food is mostly appropriated to the fattening of hogs and other domestic animals; and, in particular instances, supplies the place of beans, as the provender of labouring horses; but care should be taken, when used in this way, that they are sufficiently dry, as, when given in the green state, they are said to produce the girpes, and other bowel complaints, in those animals. Bannister, after observing that the hauin is a very wholesome food for cattle of every kind, he has especially a considerable denomination in the market, the uses to which they may be applied being so many and so various. The boilers, or yellow peas, always go off briskly; and the hog-peas usually sell for 6d. or is. per quarter more than beans. For feeding swine the pea is much better adapted than the bean, it having been demonstrated by experience, that hogs fat more kindly when fed with this grain than with beans; and, what is not easy to be accounted for, the flesh of swine which have been fed on peas, it is said, will swell in boiling, and be well tasted; whilst the flesh of the bean-fed hog will shrink in the pot, the fat will boil out, and the meat be less delicate in flavour. It has been observed by some farmers who are in this instance, that instead of their hogs eating their peas on peas and barley-meal; and if they have no peas of their own growth, they rather choose to be at the expense of buying them, than suffer their hogs to eat beans. Nay, so far, says he, do some of them carry their hogs on pea, and feed grey peas for the greater part, as bearing too near an affinity to the bean, and therefore reserve their growths of white peas solely for hog fattening.

5218. In boiling split peas, some samples, without reference to variety, fall or mould down freely into pulp, while others continue to maintain their form. The former are called boilars. This property of boiling depends on the soil; still land, or sandy land, that has been limed or manured, or to which gypsum has been applied, produces peas that will not melt in boiling, no matter what the variety may be. The same effect is produced on beans, on kidney-beans in the pod, and indeed on the seeds and pods of all leguminous plants having a great tendency to absorb gypsum from the soil. To counteract this fault in the boiling, it is only necessary to throw into the water a small quantity of subcarbonate of soda. (Bull. de Sci. Agr. Feb. 1828.)

5219. Pea straw cut green and dried is reckoned as nourishing as hay, and is considered excellent for sheep.
5220. *In the saving of any particular sorts of peas for seed, they should be carefully looked over while in flower, in order to draw out all such plants as are not of the right kind; as there will always be, in every sort, some rogues, which, if left to mix, will cause degeneration. As many rows as may be thought sufficient to furnish the desired quantity of seed should then be marked out, and left till their pods turn brown, and begin to split, when they should immediately be gathered up, with the haulm; and if the farmer has not room to stack them till winter, they may be threshed out as soon as they are dry, and put up in sacks for use: but particular care should be taken not to let them remain too long abroad after they are ripe; as wet would rot them; and heat, after a shower of rain, makes their pods burst in such a manner that the greater part of their seeds would be lost.*

5221. *The diseases of peas are few, and chiefly the worm in the pod and the fly on the leaves and flower. They are also liable to be mildewed or blighted. None of these evils, however, are very common; and there is no known way of preventing them but by judicious culture. Late sown peas are particularly liable to be injured by the mildew and Aphis; and should either of these attack the plant before the pods are filled, they invariably fail. In 1826 almost all the crops of peas were destroyed by the Aphiides, so that they were mown for the haulm only.*

Sect. II. *The Bean. — Vicia Faba L.; Diadphila Decandria L., and Leguminosee J. Feverole, Fr.; Bohn, Ger.; Fava, Ital.; and Altejanas, Sp.*

5222. *The bean is a valuable field plant, as affording food for live stock, and in part for man. It is said to be a native of Egypt; but, like other long domesticated plants, its origin is very uncertain. It has been cultivated in Europe and Asia long out of mind. Beans have been long known in Britain; but it is only of late years that they were extensively cultivated upon general soils, being formerly considered as adapted only to rich and moist clays. At that time they were all sown according to the broad-cast system; in which way, instead of benefiting the ground, they were of inculcable detriment. Weeds got away at the outset, and in dry seasons often ruined the crop; whilst in every season the grass or perennial weeds which happened to be in the ground increased in strength and in quantity, the openness of the bean crop at bottom allowing them to thrive without interruption.*

5223. *The drilling of beans with a small mixture of peas is now become a general practice in every well cultivated district of the north, more particularly in those where soil and climate permit the practice to be successfully executed. In this way not only heavy crops are raised, but, what is of great importance, the ground is kept constantly in good order, provided suitable attention is bestowed upon the cleaning process. This is generally carried on by horse-hoeing the crop at different times, so long as the hoe can be used without doing damage; and in this way an able auxiliary is brought forward to the assistance of summer fallow, whereby less stress need be laid upon that radical process than otherwise would be indispensably necessary. (Brown.)*

5224. *The varieties of the bean may be included under two general heads, — the white or garden beans, and the grey or field beans.*

5225. *Of the white or garden beans (Feverole de marais, Fr.) sown in the fields, the mazagan and long-pod are almost the only sorts. Of the grey beans, that known as the horse bean, the small or ticks, and the prolific or Heligoland, are the chief sorts. New varieties are procured in the same manner as in other plants. A variety is in use in some parts of Lincolnshire, called the winter bean (Feverole d'hiver, Fr.). It is planted in October in the usual manner, and is ready to harvest in the last week in July or the first week in August. They are said to have been introduced from the Continent in 1825. We have lately seen a field of this bean at the Oaks Farm, near Woking, in Surrey, which was planted in October 1829, and in full bloom May 12th following. This circumstance, after so severe a winter, is a proof to us that this is a very valuable variety. (Gard. Mag. vol. vi.)*

5226. *In the choice of sorts, tick beans are supposed by some farmers to be more productive than horse-beans; but the latter grow higher in the stem, and produce a more stagnant state of the air, or smother the land more, consequently are the most suitable for the stronger sorts of soil; and Young remarks, that “the common little horse-bean has the advantage of all others in being more generally marketable; for in certain situations it is not always easy to dispose of ticks, Windsors, long-pods, and various other large sorts. They also grow higher, shade the ground in summer more from the sun, and yield a larger quantity of straw, which makes excellent manure. But some of the other sorts are generally supposed to yield larger products. In purchasing beans for seed, care should be taken to choose such as are hard and bright, without being shrivelled in their appearance.”*

5227. *The best soils for beans are clays and strong loams. On such soils they generally succeed wheat or oats, but sometimes also clover leys. Turnip soils or sands are by no means proper for them.*

5228. *In the preparation of the soil much depends on the nature of the land and the state of the weather; for as beans must be sown early in the spring, it is sometimes impossible to give it all the labour which a careful farmer would wish to bestow. It must also be regulated in some measure by the manner of
sowing. In all cases it ought to be ploughed with a deep furrow after harvest or early in winter; and as two ploughings in spring are highly advantageous, the winter furrow may be given in the direction of the first. Before sowing in spring the land should be tilled; and the second ploughing is to be given across the ridges, as early in spring as the ground is sufficiently dry; and the third furrow either forms the drills or receives the seed. (Supp. E. Brat. art. Agr.)

5321. The best way, according to Brown, is to apply the dung on the stubble before the winter furrow is given, which greatly facilitates the after process. Used in this way, a fore stock must be in hand; but when the farmer is not so well provided, spring sowing becomes necessary, though evidently of less advantage. At that season it may either be put into the drills before the seed is sown, or spread upon the surface and ploughed down, according to the nature of the drilling process which is meant to be adopted. Land dunged to beans, if duly hoed, is always in high order for carrying a crop of wheat in successive years; or perhaps better wheat, both in respect of quantity and quality, may be cultivated in this way than in any other mode of sowing.

5322. The climate most favourable to the bean is one neither very dry nor very moist; the first brings on the fly, and the last prevents the setting of the blossoms. In general, however, a dry summer is most favourable to the production of seed, and moist weather to the growth of the haulm.

5323. The time of sowing beans is as early as possible after the severity of winter is over; in the south, sometimes in January, but never later than the end of March, as the ripening of the crop and its safe harvesting would otherwise be very precarious in this climate. Bannister thinks that the proper time for planting beans in Kent is towards the latter end of January or early in the following month; though this business may be continued with advantage till the middle or latter end of March, if the weather should prevent their being got in at an earlier season: but in general it is best to embrace the first opportunity of sowing them after Candlemas, as they often miscarry when the season is procrastinated beyond that time, especially if a dry summer should succeed.

5324. The mode of sowing is almost always in rows. Though still sown broadcast in several places, and sometimes dibbled, they are for the most part drilled by judicious cultivators, or deposited after the plough in every furrow, or only in every second or third furrow.

5325. In the latter method the crop rises in rows, at regular intervals of nine, eighteen, or twenty-seven inches, and the hand-hoe ought invariably to be employed; but it is only where the widest interval is adopted that the horse-hoe can be used with much effect in their subsequent culture.

5326. There are two modes of drilling beans. In one of these the lands or ridges are divided by the plough into ridgelets or one bout stitches, at intervals of about twenty-seven inches. If dung is to be applied, the seed ought to be first deposited, as it is found inconvenient to run the drill-machine over the dung. The ridgelets, one row of beeps serving for three or five ridgelets, and it is evenly spread and equally distributed among them in a way that will be more minutely described when treating of the culture of turnips. The ridgelets are next split out or revered, either with the spade or of the common plough or hoe without the fence; by which method both the seed and the manure are perfectly covered. When beans are sown by the other method, in the bottom of a common furrow, the dung must be previous spread over the surface of the winter or spring ploughing. Three ploughs then start in succession, one immediately behind another, and acrill'horar either follows the middle one, at which time the beans are sown; every third furrow, or at from twenty-four to twenty-seven inches asunder, according to the breadth of the furrow. Rice.

5327. Another approved way of sowing beans, when dung is applied at seed-time, is to spread the dung and the seeds in the first shallow furrow; and the beans are drilled along the bottom of this furrow by the drill-machine. Whichever of these modes of sowing is followed, the whole field must be carefully laid dry, by means of channels formed by the plough, and when necessary by the shovel; for neither then nor at any former period should water be allowed to stagnate on the land.

5328. The dibbling of beans is considered by Arthur Young as an excellent method when well performed; but the grand objection to it is the difficulty of getting it well done.

5329. When dibbling becomes the common husbandry of a district, the workmen find that great earnings are to be made by it, and this is much too apt to make them careless and eager to earn still more; and if a workman is not paid the constant and reasonable price, by them supposed not to have the height of holes so shallow that the first peck of a rook's bill takes the seed, and acres may be destroyed if the breed of those birds be encouraged. Boys are employed for weeks together to keep the fields, but all works that depend on boys are horribly neglected, and the farm suffers materially; however, if there are two and a half or two and a quarter three inches deep, it is not so easily eradicated. In some districts, as Middlesex, Surrey, &c., the method is to plant this pulse in rows struck out by a line, by which a great saving is made in the article of seed, a circumstance which is thought to be of some material importance; however, the extraordinary charge of this mode of husbandry; and thus far it may be fairly argued that the method of planting beans by the dibber is greatly to be preferred to that of sowing the seed at random.

The economy of this agricultural process is thus explained:—The rows are marked out one foot asunder,
and the seed planted in holes made two inches apart: the lines are stretched across the lands, which are for convenient parts planted so that when one row is to be moved by a regular measurement to the distance required, and the same method pursued till the field is completed. The usual price for this work is ninepence per peck, and the allowance two bushels per acre. Great confidence must necessarily be reposed in the people who transplant the plants of beans by the plough, and it is considered very necessary to give sufficient time for the weeds to grow beyond the reach of either hoe, should be pulled up with the hand. The same operations are repeated as often as the condition of the land, in regard to cleanliness, may require.

524. Before the introduction of the horse-hoe, which merely stirs the soil, and cuts up the weeds, a common small plough, drawn by one horse, was used in working between the rows and is still necessary where root-weeds abound. This plough goes one bolt, or up and down in each interval, turning the earth from the beans, and forming a ridglet in the middle; then hand-hoes are immediately employed; and, after some time, a scythe, with a hand-hoe succeeding, to destroy any fresh growth of weeds. The same plough, with an additional mould board, finally splits open the intermediate ridglet, and lays up the earth to the roots of the beans on each side. The benefit of laying up the earth in this manner, however, is alleged to be counterbalanced by the trouble which it occasions, in harvest, when it is difficult to get the reapers to cut low enough; and it may be properly dispensed with, unless the soil is very wet and level.

524. In most warm seasons, this grain hardly ever ripens effectually; and it is exceedingly difficult to get the straw into a proper condition for the stack. In such cases, it has been found of advantage to switch off the succulent tops with an adze, or the blade set in a wooden handle, with which one man can easily top dress two acres a day. This operation, it is said, will occasion the crop to be ready for reaping a fortnight earlier, and also, perhaps, a week sooner ready for the stack-yard after being reaped.

524. Before reaping beans the grain ought to be tolerably well ripened, otherwise the quality is impaired, whilst a long time is required to put the straw in such a condition as to be preserved in the stack. In an early harvest, or where the crop is not weighty, it is an easy matter to get beans sufficiently ripened; but, in a late harvest, and in every one where the crop takes on a second growth, it is scarcely practicable to get them thoroughly ripened for the sickle. Under these circumstances, it is unnecessary to let beans stand uncut after the end of September, or the first of October; because any benefit that can be gained afterwards, is not to be compared with the disadvantages that accompany a late wheat seed-time.

524. Beans are usually cut with the sickle, and tied in sheaves, either with straw ropes, or with ropes made from peat sown along with them. It is proper to let the sheaves lie untied several days, so that the winning process may be more easy, and when tied, to set them up on end, in order that full benefit from the air may be obtained, and the grain kept off the ground. (Brown.)

524. Beans are sometimes mown, and, in a few instances, even pulled up by the roots. They should in every case be cut near as the ground as possible, for the sake of the straw, which is of considerable value and is often placed on the land. The best placed on the land, if afterwards set down with a scythe, may then lie for a few days to wither, and afterwards bound and set up in shocks to dry, but without any head sheaves. (Supp. 8.)

524. Beans are stacked either in the round or oblong manner; and it is always proper, in the northern counties at least, if the stack is large, to construct one funnel or more to allow a free circulation of air.

524. The threshing of beans is nearly as easy as that of peas. threshing them by a machine may be considered advantageous as breaking the coarser ends of the straw, and separating the earth from their root-ends, or roots, if they have been reaped by pulling.

524. The produce of beans, when proper management is exercised, and where diseases have not occurred, is generally from twenty-five to thirty-five bushels per acre. Donalson says, that a crop of beans, taking the island at large, may be supposed to vary from sixteen to forty bushels, but that a good average crop cannot be reckoned to exceed twenty. In Middlesex, Middleton tells us, that bean-crops vary from ten to eighty bushels per acre. They are rendered a very precarious crop by the ravages of myriads of small black insects of the Apthi kind. The lady-birds (Coccinella) are supposed to feed on them, as they are observed to be much among them. Foot says, the average produce is from
three and a half to four quarters per acre. In Kent, A. Young thinks, they probably exceed four quarters; but in Suffolk, he should not estimate them at more than three; yet five or six are not uncommon.

5250. The produce in haulm, in moist seasons, is very bulky.

5251. In the application of beans, the grain in Scotland is sometimes made into meal, the finer for bread, and the coarser for swine; but beans are for the most part applied to the purpose of feeding horses, hogs, and other domestic animals. In the county of Middlesex, all are given to horses, except what are preserved for seed, and such as are podded while green, and sent to the London markets. When pigs are fed with beans, it is observed that the meat becomes so hard as to make very ordinary pork, but good bacon. It is also supposed that the mealmen grind many horse-beans among wheat to be manufactured into bread.

5252. The flour of beans is more nutritious than that of oats, as it appears in the fattening of hogs; when, according to the respective parts of these two articles, Dr. Brown suspects that peas and beans generally supply a cheaper provender for horses than oats, as well as for other domestic animals. But as the flour of peas and beans is more oily, he believes, than that of oats, it may in general be somewhat more difficult of digestion; hence, when a horse has taken a stomachful of peas and beans alone, he may be less active for an hour or two, as his strength will be more employed in the digestion of them than when he has taken a stomachful of oats. A German physician gave to two dogs, which had been kept a day fasting, a large quantity of flesh food; and then taking one of them into the fields, hunted him with great activity for three or four hours, and left the other by the fire. An emetic was then given to each of them; and the food of the sleeping dog was found perfectly digested, whilst that of the hunted one had undergone but little alteration. Hence it may, he says, be found advisable to mix bran of wheat with the peas and beans, a food of less nutriment, but of easier digestion; or to let the horses eat before or after them the coarse tussocks of grass and clover, which remain in moist pastures in the winter; or, lastly, to mix finely cut straw with them. It is observed in the fifth volume of The Both Papers, that it has been found by repeated experience, that beans are a much more hearty and profitable food for horses than oats. Being out of old oats the two last springs, the writer substituted horse-beans in their stead. In the room of a sack of oats with chaff, he ordered them a bushel of beans with chaff, to serve the same time. It very soon appeared the beans were superior to the oats, from the life, spirit, and sleekness of the horses.

5253. Bean straw, when mixed with peas, Brown considers as affording almost as much nourishment when properly harvested as is gained from hay of ordinary quality; when it is well got the horses are fonder of it than of pea straw. It should either be given when newly threshed, or else stacked up and compressed by treading or coverings, as the air is found materially to affect both its flavour and nutritive quality.

5254. The produce of beans in meal is, like that of peas, more in proportion to the grain than in any of the cereal grasses. A bushel of beans is supposed to yield fourteen pounds more of flour than a bushel of oats, and a bushel of peas eighteen pounds more, or, according to some, twenty pounds. A thousand parts of bean flour were found, by Sir H. Davy, to yield 570 parts of nutritive matter, of which 426 were mucilage or starch, 103 gluten, and 41 extract, or matter rendered insoluble during the process.

5255. The diseases of beans are, the rust, mildew, black fly or Aphides, and in consequence the honey dews.

5256. Aphides, when they live on beans, are of a dirty bluish-black colour, similar to those on the elder and cherry. The larvae of the Cecenilla septempunctata, as well as the perfect insects, devour the Aphides. Several of the small summer birds, viz. largest willow-wren, middle, and smallest wren, white-throat, lesser white-throat, black-cap, and Dartford warbler, also live on them. The Aphides of beans are brought on by very dry weather; they are most prevalent on the summits of the plants, and some have attempted to mitigate the evil by cutting off the tops. In general, however, the disease is without remedy, either preventive or positive. In extreme cases they destroy the leaves, stalks, and fruit; and when this is foreseen, the best thing the farmer can do is to mow the crop or plough it down, and prepare the land for wheat or otherwise, according to the rotation.

5257. The tare, vetch, or rift (Vicia sativa, fig. 742.), has been cultivated for its stem and leaves from time immemorial. It is considered as a native plant, and is found wild also in China and Japan. Ray, in 1686, informs us, that the common tare or rift was then sown almost all over Europe; that it was chiefly used in England, mixed with peas and oats, to feed horses: but that it was sometimes sown separately for soiling cattle, and was reputed to cause milk cows to yield much milk. The tare, Brown observes, is of hardy growth, and, when sown upon rich land, will return a large supply of green fodder for the consumption of horses, or for fattening cattle.

5258. The varieties of tares are chiefly two, the winter and spring tare; both have local names, as gorse vetch, rath ripe vetch, &c. Some consider them as distinct species, but this is doubtful.

5259. As the result of an experiment tried for two years at Dury, in Suffolk, Professor Martin of the Botanists, that there appears a material difference in the constitution, if we may so call it, of the two tares in question. Not to say anything of a trifling difference in the colour and size of their seeds, the only visible mark of distinction seems to be a disparity in the first leaves of the upright stalks, which in the spring
tare are elliptic, and rounded or notched at the end, but in the winter tare linear and drawn to a point. The methods which follow, and which are the same in both vetches. But, whatever the difference may be, it is evident that the seeds of the two sorts ought to be kept separate; since each sown out of its proper season is found not to prosper.

5. New varieties of tare may be obtained by the usual means; and it is thought that some of the numerous species of this plant, which are natives of Europe, may be cultivated with advantage. The French cultivate a variety which they call *Vicia lutea*, or *Lentille du Canada*, *Vicia sativa alba*. They include also among their *Vicia lutea* *Vicia angustifolia*, *Cracea*, *Pedio* *Cracea*, *biennis*, *sépnum*, and *latifolium*. *Vicia nana* and *veratitidea* are cultivated in Germany. Dr. Anderson has recommended the *V. sépnum*; and a writer in *The Botanical Transactions*, the *V. Cracea*. Some species of *Lathyrus*, *Rothus*, and *Ervum* might probably also be tried with success.

5. In choosing between the spring and winter tare, every thing depends on the intention of the cultivator. If he wishes to have early feed, the winter variety is undoubtedly to be preferred; but where the land is foul and requires to be two or three times ploughed in spring, or where a late crop is desired, or a crop for seed, then the spring variety will generally deserve the preference.

5. The soil preferred by the tare is a clay, but they will grow in any rich soil not over dry. In a moist climate, the haum grows so luxuriant as to rot at bottom; and in one over dry it is deficient in length. A dry season, however, is on the whole more favourable than a moist one, as this crop soon covers the surface.

5. The preparation of the soil seldom consists of more than one ploughing, if for autumn sowing; and of a winter and spring ploughing, when to be sown in spring. If in the latter case the land is very foul, several ploughings are given, or one ploughing and several stirrings with the cultivator. In general, tares succeed some of the corn crops. In England manure is sometimes given either with a view to earthing them off early, and following with a crop of turnips, or to enriching the soil for a crop of wheat.

5. The time of sowing depends on the kind of tare, and the purpose in view.

5. The winter variety is sown in September and October; and the first sowing in spring ought to be as early as possible, that to be cut for green hay, and if they are to be required for seed, and the latter end of May will answer well, provided crops in succession, from the first to the last-mentioned period, be regularly cultivated. Instances are not wanting of a full crop being obtained even when the seed was sown so late as the middle of June, though sowing so late is a practice not to be recommended.

5. In Middlesex, the winter sowings are commenced about the beginning of August; in the northern counties no winter sowings are made, as the tare there will not endure the severity of that season.

5. The mode of sowing is mostly broad-cast, which should be performed as evenly as possible over the surface of well-prepared land; the seeds being afterwards covered in by proper harrowing, in order to prevent their being picked up by birds, and ensure their perfect vegetation and growth. It has been suggested, however, that, in rich clean soil, it is probable the row-method would succeed well with this sort of crop, which, as Marshal states, is the practice in some of the southern districts of the island. After the seed is sown, and the land carefully harrowed, a light roller ought to be drawn across, so that the surface may be smoothed, and the sown permitted to work without interruption. It is proper also to guard the field for several days against the depredations of pigeons, who are remarkably fond of tares, and will pick up a great part of the seed, unless constantly watched.

5. The quantity of seed to an acre is from two and a half to three and a half bushels, according to the time of sowing, and to whether they are to be consumed green or left to stand for a crop.

5. When tares are intended for seed, less seed is required than when they are grown for soil ing or for drying the haum. A writer in *The Farmer's Magazine* (vol. I) has suggested, that the most productive method of sowing this crop, when intended for seed, is to mix them amongst beans when drilled, at the rate of one flint of tares to one ball of beans. From trials made it is ascertained, it is thought that the quality of the tares is vastly improved by being blended with beans, as, by clinging to the latter, they are kept from the ground, and enjoy the full benefit of the sun for ripening them in a perfect manner; and they are in this way much easier harvested than when sown by themselves. They answer, at the same time, for lands to tie the principal crop; and the produce may, on an average of seasons, be considered as at least double. A little rye sown with winter tares, and a few oats with the spring sort, not only serve to support the weak growing stems of the tares, but add to the bulk of the crop by growing up through the tares.

5. In the choice of the seed it is hardly possible to distinguish the grain of the winter from that of the spring variety: the former is alleged to be rather smaller and lighter coloured; but the only reliance must be on the necessity of the variety of the trump seed, and a sample free from the seeds of weeds, will of course be selected, whatever be the variety.

5. The after culture given to tares consists merely in pulling out the larger weeds, unless they are in rows, in which case the horse or hand hoe is applied; or intended for seed, in which case weeding must be more particularly executed.

5. In reaping tares for soil ing they ought always to be cut with the scythe, as the sickle, by breaking asunder the stalks, and tearing up a number by the roots, renders the second crop of little value. When necessary, early, they may in a moist season produce three mowings, but generally two. In reaping tares for seed, they may be either mown or taken with the sickle, and treated like peas in drying, stacking, and threshing.

5. Tares are eaten off the ground in some places by different kinds of live stock, particularly by sheep; and as the winter-sown variety comes early in spring, the value of this rich food is then very considerable. The waste, however, in this way, even
though the sheep are confined in hurdles, must be great; and still greater when consumed by horses or cattle.

5273. Tare crops are sometimes made into hay, in which case more attention is found necessary than in those of most of the artificial grasses, as wet is more injurious to them, and they require more sun and air; but in other respects they demand the same cautious management, in order to preserve the foliage from being lost. The time for cutting for this purpose is, according to the author of The Synopsis of Husbandry, when the blossoms have declined and they begin to fall and lie flat. When well made, the hay is of the best and most nutritious quality.

5274. The produce of tares cut green is, according to Middleton, ten or twelve tons per acre, which is a large crop; and when made into hay about three tons per acre, which shows the disadvantage of making these crops into hay. It is found that the spring tare-crops are lighter, and most liable to be injured by a dry season.

5275. The produce in seed is likewise found to be considerable, being by some stated at from three to six sacks; but in other instances forty bushels, or more, have been obtained from the acre.

5276. In the application of tares they are found to be a hearty and most nourishing food for all sorts of cattle.

5277. Cows give more butter when fed with this plant than with any other food whatsoever. Horses thrive better upon tares than they do upon clover and ryegrass; and the same remark is applicable to the fattening of cattle, which feed far upon this article of green fodder than upon any kind of grass or succulent with which we are acquainted. Danger often arises from their eating too much, especially when podded; as colics, and other stomach disorders, are apt to be produced by the excessive loads which they devour. Perhaps a great quantity of fresh air is contained in this vegetable; and, as heavy hay is rarely sold upon them without any other food. This plant maintains more stock than any other plant whatever. Upon one acre Davis maintained four horses in much better condition than upon five acres of grass. Upon eight acres he has kept twelve horses and five cattle; and three months of the hay is equal to this excellent plant." This statement must be coupled with the usual produce of turnips in Sussex, 10 or 15 tons per acre: hence the supposed superiority of tares to every other green crop. Tares cut green, Professor Thacker observes, draw no nourishment from the soil whatever; while made into hay, they afford a fodder preferred by cattle to pea straw, and more nutritious than hay or any other herbage.

5278. The use of the grain of tares is generally for reproduction; but they are also given to pigeons, by which they are highly relished, and it is thought they would form a very good food for poultry. In Germany they are given to horses, cows, sheep, and swine.

5279. The diseases of tares are so few as to be of no consequence. A crop is sometimes, but rarely, lost by mildew.

Sect. IV. Various Legumes which might be cultivated in British Farming.

5280. The lentil, kidney-bean, and chick pea are grown both in France and Germany, as field plants, for their seeds, which are used as food. They are by no means likely to become articles of general culture in Britain; but it is worth while to know that they may be cultivated here instead of being imported, and also that they form very excellent articles of human subsistence.

5281. The lentil is the Eruvum Lens L.; Lentilion, Fr.; Lentzen, Ger.; and Lenticea, Ital. (fig. 743.) It is a legume of the greatest antiquity, being in esteem in Euxin's times, and much prized in eastern countries since. In Egypt and Syria, they are parched in a frying-pan and sold in the shops, and considered by the natives as the best food for the poor who undertake long journeys. The lentil of France is named a grain lentil; but the lentil of Provence, which is almost as large as a pea, with luxuriant straw, and more fit to be cultivated as a tarne than as food for man. The French have also a winter lentil, Lentilion d'hiver; and they cultivate the Eruvum Ervilia, Lentilie Eruvle, Eruvle Eruvle, and the Eruvle d'Eure, and the Eruvle d'Auvergne. The Spanish lentil,--Grase cultivado, Lentile d'Espagne, Fr., Lentile, Span., is the Lathyris sativus, (fig. 744.) It is sometimes grown in gardens in this country, and occasionally in the fields in the west. The lentil of Canada, Lentile du Canada, Fr., is the

Vicia pisiformis Lin. (fig. 745.) Vicia Ervilia Wild., Eruvle tetrapterum Lin., and E. hissitum Lin., are also cultivated in some places as lentils; and indeed the seeds of all the tribe Vicia (Encyclopaedia of Plants, p. 1625.) may be eaten by man.

5283. A dry, warm, sandy soil is requisite for the lentil; it is sown rather later than the pea, at the rate of a bushel or a bushel and a half to the acre; in other respects its culture and harvesting are the same,
and it ripens sooner. The lentil, Young observes, is a crop not uncommon about Chesterford in Essex, where they sow a bushel an acre on ploughing in the beginning or middle of March. It is there the custom to make hay of them, or seed them for cutting into chaff for rough-meal for sheep and horses, and they sow them on both heavy and dry soils. It is, however, added, that the whole country is of a calcareous nature. It is likewise stated, that attention should be paid not to water horses soon after eating this sort of food, as they are apt to love them. They are asserted to be cultivated for the same purpose in Oxfordshire, and probably in other districts.

5254. The produce of the lentil in grain is about a fourth less than that of the tare; and in straw it is not a third as much, the plants seldom growing above one foot and a half high. The straw is, however, very delicate and nourishing, and preferred for lambs and calves; and the grain on the Continent sells at nearly double the price of peas. Einhoff obtained from 2840 parts of lentils, 1260 parts of starch, and 1435 of a matter analogous to animal matter.

5255. The use of the lentil on the Continent is very general, both in soups and dressed with a butter sauce as haricot. They are imported from Hamburg, and sold in London for the same purpose.

5256. The chick pea (Potoschica Ganacum, Fr.; Cicer arietinum, fig. 52.), grows naturally in the south of Europe, and is cultivated there for the same purposes as the lentil, but it is too delicate for field culture in this country.

5257. The kidney bean (Phaseolus vulgaris L.; Haricot, Fr.; Schminkbohn, Ger.; and Fagiuolo, Itat.) is a native of India, but ripens readily in dry summers in most parts of Britain. Its culture has been hitherto confined to gardens; but it may be grown equally well in dry, warm, rich, and sheltered soils, being grown in the fields of Germany, Switzerland, and in similar climates. The sort generally used for this purpose is the small dwarf white; the ground is prepared by several stirrings, and the seed is sown in rows eighteen inches or two feet asunder in the beginning of May. The ground is hoed and weeded during the summer, and the crop is ripe in August. It is usually harvested by pulling up the plants, which, being dried, are stacked or threshed. The hull is of little bulk or use, but the seed is used in making the esteemed French dish called haricot, which it is desirable thecottagers of this country should be made acquainted with. There is, perhaps, no other vegetable dish so cheap and easily cooked and at the same time so agreeable and nourishing. The beans are boiled and then mixed with a little salt butter or other fat, and a little milk or water and flour. From 28-40 parts of kidney bean, Einhoff obtained 1885 parts of matter analogous to starch, 853 of vegeto-animal matter, and 799 parts of mucilage. Haricots and lentils are much used in all Catholic countries during Lent and minore days, as they, from their peculiar constituents, form so excellent a substitute for animal food.

During the prevalence of the Roman religion in this country, they were probably much more generally used than at present; as reformations are often carried farther than is necessary. Possibly lentils may have been left off by Protestants, lest the use of them should be considered a symptom of popery.

5258. The white lupine (Lupin blanc, Fr.; Lupinus Albus L., fig. 746) was cultivated by the Romans as a legume, and is still occasionally grown in Italy and France. The seeds were formerly, and are sometimes now, used as food; but more generally the whole plant is mown and given as herbage to cattle, and sometimes the crop is ploughed down as manure.

** Chap. IV. **

**Plants cultivated for their Roots or Leaves in a recent State as Food for Man or Cattle.**

5289. Plants cultivated for their roots or leaves are various, and most of them are adapted both for human food and that of domestic animals; but some are chiefly or entirely grown for the nurture of live stock. The plants which we include under this head, are the potato, turnip, carrot, parsnip, beet, cabbage tribe, lettuce, and chicory. The culture of roots may be considered a branch of farming almost entirely of modern origin, and more peculiarly British than any other department. Turnips were cultivated by the Romans, and in modern times brought into notice as objects of field culture in the last century; but they were most imperfectly managed, and of very little utility in agriculture till their culture was undertaken by the British farmer. The potato, carrot, and parsnip were also first cultivated in the fields of this country. Friable or light soil, superior pulverisation and manuring, the row-method, and careful after-culture, are essential to the maturation of the plants to be treated of in this Chapter; and hence the importance of such crops as preparations for those of the bread corns.
The nutritive products of these plants are thus given by Sir H. Davy: —

**SECTION I. The Potato.** — **Solanum tuberosum L.;** **Pentandria Monogynia L.;** and **Solanoe J. Pomme de Terre, Fr.;** **Cartoffel, Ger.;** **Tartiffl or Pomo di Terra, Ital.;** and **Patata, Span.**

The potato is ascertainment to be a native of South America, having been found wild both in Buenos Ayres and in Chili; though Humboldt was very doubtful if that could be proved: he admits, however, that it is naturalised there in some situations. Sir J. Banks (Hort. Trans. vol. i. p. 8.) considers that the potato was first brought into Europe from the mountainous parts of South America, in the neighbourhood of Quito, where they were called papas, to Spain, in the early part of the sixteenth century. From Spain, where they were called batatas, they appear to have found their way first to Italy, where they received the same name with the truffe, taratufi. The potato was received by Clusius, at Vicenza, in 1588, from the governor of Mons, in Hainault, who had procured it the year before from one of the attendants of the Pope's legate, under the name of taratufi, and learned from him that it was then in use in Italy. In Germany it received the name of cartoffel, and spread rapidly even in Clusius's time.

To England the potato was brought from Virginia by the colonists sent out by Sir Walter Raleigh in 1584, who returned in July 1586, and "probably," according to Sir Joseph Banks, "brought with them the potato." Thomas Herriot, in a report on the country, published in his "Collection of Voyages," (vol. i. p. 17.), describes a plant called openack (not openacke), as in the Hort. Trans., with "roots as large as a walnut, and others much larger; they grow in damp soil, many hanging together, as if fixed on ropes; they are good food, either boiled or roasted." Gerarde, in his Herbal, published in 1597, gives a figure of the potato, under the name of the potato of Virginea, whence, he says, he received the roots; and this application it appears to have retained, in order to distinguish it from the batatas, or sweet potato (Convolvulus Batatas), till the year 1640, if not longer. "The sweet potato," Sir Joseph Banks observes, "was at least as early known in England as any thing long before the introduction of our potatoes: it was imported in considerable quantities from Spain and the Canaries, and was supposed to possess the power of restoring decayed vigour. The kissing censits of Falstaff, and other confections of similar imaginary qualities, with which our ancestors were doped, were principally made of this and ofкрипнo roots."”

"The potato was first planted by Walter Raleigh, on his estate of Youghall, near Cork, and, Gough says, was "cherished and cultivated for food" in that country before its value was known in England; for, though they were soon carried over from Ireland into Lancashire, Gerarde, who had this plant in his garden at Rokeby, in 1597, under the name of Batata, or Batatas, recommends it as a delicacy, of bold, but not as common food. Parkinson mentions, that the tubers were sometimes roasted, and steeped in sack and sugar, or baked with marrow and spices, and even preserved and candied by the comfort-makers. There is a tradition among the peasantry in the county of Galway, that the potato was introduced there previous to its being known in any other part of Ireland, owing to a vessel with some of the roots on board having been wrecked on their coast, and a few of the roots having been roasted by children who found them, they were so much approved of, as to induce the planting of the remainder.

For encouraging the cultivation of potatoes, with the view of preventing famine, the Royal Society took some measures in 1653. Still, however, although their utility as an article of food was better known, no high character was bestowed on them. In books of gardening, published towards the end of the seventeenth century, a hundred years after their introduction, they are spoken of rather slightly. "They are much used in Ireland and America as bread," says one author, "and may be propagated with advantage to poor people." — "I do not hear that it hath been essayed," are the words of another, "whether they may not be propagated in great quantities, for food for swine or other cattle." Even the enlightened Evelyn seems to have entertained a prejudice against them: "Plant potatoes," he says, writing in 1699, "in your worst ground. Take them up in November for winter spending; there will enough remain for a stock, though ever so exactly gathered." But the use of potatoes gradually spread, as their excellent qualities became better understood. It was near the middle of the eighteenth century, however, before they were generally known over the country; since that time they have been most extensively cultivated. In 1760, it was found that, in the county of Essex alone, about 170 acres were planted with potatoes for the supply of the London market. This must form, no doubt, the principal supply; but many fields of potatoes are to be seen in the outlying districts and in the country, and many thousands are annually imported from a distance. In every county in England, it is now more or less an object of field culture.

**Potatoes, as an article of human food, are next to wheat, of the greatest importance in the eye of the political economist.**

**From no other crop that can be cultivated will the public derive so much food as from this valuable sculent; and it admits of demonstration, that an acre of potatoes will feed double the number of people that can be fed from an acre of wheat.** Potatoes are also a nourishing and healthful food, relished by almost every palate; and it is believed there is hardly a dinner served for six months in the year without them, in any part of the kingdom. Notwithstanding all these things, and they are of great importance in one point of view, we are doubtful whether potatoes can be placed so high in the scale as
They require a great deal of manure, while, generally speaking, little is returned by them; they are a bulky unhandy article, troublesome in the lifting and carrying processes, and interfering with the seed season of wheat, the most important one to him; and, from particular circumstances, they cannot be vended unless raised in the vicinity of large towns: hence they are in most respects an unprofitable article to the farmer. The rent manure, or the profit which potatoes will return in feeding beasts; and here, we apprehend, the result will be altogether in favour of turnips, and rutsåga, as the most profitable articles for that purpose.

5028. That which is called the yam, or Sarranam potato, was formerly considered of importance to the farmer, as an assistant to his turnip crop, or rather a sucedaneum, which is of material benefit when turnips are consumed; but as this variety cannot be used as human food, the extension of its culture cannot be recommended. By cultivating any of the good eating sorts for the use of cattle, a sucedaneum may be had without expenses in year, besides that of composition.

5298. The value of potatoes as a fallow crop, and as an article of food for cattle compared with turnips and cabbages for the same purposes, Marshal observes, may be considered thus:

5299. Potatoes are more nutritious; and, in the opinion of those who have used them, fatten cattle much quicker than either turnips or cabbages. Potatoes, too, being secured from the severities of winter, are a more certain article of fattening than turnips or cabbages; both of which are liable to perish under an alternation of frost and thaw. They are more partible than turnips, movable, and will suffer a continuance of snow or frost. Turnips and cabbages, if they out-winter the severities of winter, occupy the soil in the spring when it should be prepared for the succeeding crop; while potatoes, if properly laid up, are a food which may be continued without inconvenience until the crop is prepared, or the grass has acquired the requisite height for finishing them in the field. On the other hand, potatoes are a divisible-acre crop to cultivate: the planting is a tedious dirty business; and taking them up may be called the finest work of husbandry, especially in a wet autumn. A powerful argument for the extensive culture of potatoes as food for live stock is, that in seasons of scarcity they are recommended. Here, as in many other points, the opinion of Marshal and other English agriculturists is rather at variance with that of the Northumberland and Berwickshire cultivators. In Berwickshire and Roxburghshire, a crop of potatoes is often taken before turnips, by means of which the land is rendered to a fertile state.

5300. The varieties of the potato are innumerable: they differ in their leaves and hulk of haulm; in the colour of the skin of the tubers; in the colour of the interior compared with that of the skin; in the time of ripening: in being farinaceous, glutinous, or watery; in tasting agreeably or disagreeably; in cooking readily or tediously; in the length of the subterranean stolones to which the tubers are attached; in blossoming or not blossoming; and, finally, in the soil which they prefer.

501. The earliest varieties of the potato are chiefly cultivated in gardens, and therefore we shall only notice such early sorts as are grown in the field. These are

- The early kidney, the
- The nunsuch, the
- The early shaw, and
- The early champion.

5302. The late field varieties in most repute are

- The red-nosed kidney.
- The large kidney.
- Bread fruit, raised in 1810, from seed, and esteemed one of the best field potatoes, being white mealy, well tasted, and prolific.
- Lord北京大学 eye, good.
- Black skin, white interior, and good.
- Purple, very much, productive, and keeps well.
- Red apple, mealy, keeps the longest of any.
- Turnip, or purple and white skinned, an esteemed Scotch potato, prolific, mealy, exceedingly well tasted, and keeps well.

5303. The varieties grown extensively as food for live stock are

- The yam or Sarranam potato; large, red and white skinned, and the interior veined with red; flavour disagreeable, and not very suitable for being used as human food. It succeeds best on heavy lands.
- The ox noble; large, yellow without and within, very prolific, not fit to it.
- The large onion; large and prolific, white skinned, and may be used as human food.

5304. New varieties of potatoes are procured with the greatest ease. The following directions are given in a useful work on this plant:

- Pluck off the apples when the stalk has ceased to vegetate and is drying up. The seed being then fully ripe, break the apple in a hair sieve, wash the pulp clean from the seeds, and dry them in the sun; then sow the seed in beds in March, and take the potatoes up in October. They will attain the size of nutmegs, or at most be no larger than walnuts. Select the farest and best, and keep them secure from frost by thoroughly drying, and intermixing, and covering them with sifted wood or coal ashes. Plant them in April following, at the distance of twelve inches asunder; and when the plant is two inches high, hill them up with fresh earth. This may be done several times, and keep them clean from weeds. Observe when the stalks decay, some will be found decaying much sooner than others; these are the early kinds, but those that decay last are the sorts which come late. Take the potatoes which they ripen in the ordinary course of early weather, keep the product of them dry. Such as come early may be tried as soon as they are taken up, by dressing one or two; should they be approved, the remainder may be preserved; but those which are late should not be tried before January or February: some will be found at this late kind a success, very soft, and cut like scotch, which, should they have been a hearded a certain time, when they become mealy. Under each stalk you may expect to find a gallon of potatoes; these planted the third year may, perhaps, produce two sacks; and their increase afterwards will be of a very considerable rate. Thus it takes full three years to form an adequate stock. Be careful not to plant potatoes raised from seed; and, after all, it is worth preserving it, as much as can be reasonably expected. In general, the produce of the seed will resemble the parent stock; but red varieties will give both white and red off spring, and among the off spring of kettles, you will find round roots. One great advantage of raising varieties from seed is alleged to be the invigoration of the vegetative principle.

5053. Some of the earlier sorts of potatoes do not blossom, and consequently do not, under ordinary management, produce seeds. To procure blossoms and seeds from these, it is necessary, from time to time, during the early part of the summer, to remove the earth from the roots of the plants, and pick off the tubers or potatoes as they begin to form. By thus preventing the strength of the plant from being employed in forming tubers at the root, it will flow into the leaves and herbage, and produce blossoms and abundance. The president of the Royal Agricultural Society, in his cultivation of this useful art, was the first to procure seeds from some sorts of potatoes which had never before produced blossoms; and from these seeds he raised excellent varieties, some hardy and less early, others small and very early. He frequently impregnated the blossoms produced by these early potatoes with other sorts, some early and some late (in the same way in which graziers cross the breeds of cattle to improve the offspring,) and he continued in producing varieties, more early than late sorts, and more hardy and prolific than any early potatoes he had seen.
These he cultivated in his fields, deeming them preferable to all other sorts as admitting of later planting and earlier renewal; and this practice he justly considered as highly favourable to the succeeding crop of wheat.

5306. In choosing a sort or sorts of potatoes from the numerous varieties which are to be found everywhere, where the best way is, for the selector to procure samples and taste them, and to fix on what best pleases his palate. The shade is one of the best early potatoes for general field culture; and the kind is usually the best sort to be grown in succession. The Lanchashire pink is also a excellent potato; and we have never in any part of the British Isles tasted a potato equal in meallness and flavour to this variety, as cultivated round Prescot, near Liverpool. The red apple and tartan are of undoubted preference. Sufficient is never kept, or long keeping potatoes. The yam is decidedly the best potato for stock, and will produce from twelve to fifteen tons per acre.

5307. The soil in which the potato thrives best is a light loam, neither too dry nor too moist, but if rich, it is so much the better. They may, however, be grown well on many other sorts of lands, especially those of the mossy, moorly, and similar kinds, where they are free from stagnant moisture, and have had their parts well broken down by culture, and a reasonable portion of manure added. The best-flavoured table potatoes are almost always produced from a newly broken up pasture ground not manured; or from any new soil, as the site of a grubbed up copse or hedge, or the site of old buildings or roads. Repeated on the same soil they very generally lose their flavour. The yam produces the largest crops on a loamy and rather strong soil, though it will grow well on any that is deeply ploughed and well manured.

5308. In preparing the soil for potatoes, it is of much importance to free it as completely as possible from root weeds, which cannot be so well extirpated afterwards, as in the culture of turnips, and some other drilled crops, both because the horse-hoe must be excluded altogether at a time when vegetation is still very young, and as it is safe to work so near the plants, especially after they have made some progress in growth. It is the earlier time of planting, and of finishing the after-culture, that renders potatoes a very indifferently suitable for fallow, or in any season of no degree comparable to turnips. For this reason, as well as on account of the great quantity of manure required, their soil and manure to very large extent, and the large period of growth, the culture of potatoes is by no means extensive in the best managed districts. Unless in the immediate vicinity of towns, or in very populous manufacturing counties, potatoes do not constitute a regular rotation, and are raised only where to the proprietors it is absolutely necessary, either to the farmer and his servants, and, in some cases, for occasionally feeding horses and cattle, particularly late in spring. The first ploughing is given soon after harvest, and a second, and commonly a third, early in spring; the land is then laid up into ridges, from twenty-seven to thirty inches broad, as for turnips, and manured in the same manner.

5309. The best manure for the potato appears to be littery farmyard dung; and the best mode of applying it, immediately under the potato sets. Any manure, however, may be applied, and no plant will bear too large a proportion of manure; but very dry straw, rush, or sprays of trees, may be made use of with success. It is alleged, however, that recent horse manure, salt, and soapers' ashes, have a tendency to give potatoes a rank taste, and to render them scabby.

5310. The best climate for the potato is one rather moist than dry, and temperate or cool, rather than hot. Hence the excellence of the Irish potatoes, which grow in a dry, loamy, calcareous soil, and moist and temperate climate; and hence, also, the inferiority of the potatoes of France, Spain, and Italy, and even Germany. In short, the potato is grown nowhere in the world to the same degree of perfection as in Ireland and Lancashire, and not even in the south of England so well as in Scotland, and the north and western counties: all which is, in our opinion, clearly attributable to the climate.

5311. The season for planting potatoes in the fields, depends much on the soil and climate. Whether these are very dry, as they always ought to be for an early crop, the sets are usually put in the ground in March or earlier; but for a full crop of potatoes, April is the best time for planting. Potatoes, indeed, are often planted in the end of May, and sometimes even in June; but the crops, although often as abundant, are neither so mellow nor mature as when the sets are planted in April, or in the first eight or ten days of May. For seed, however, they are preferable.

5312. In preparing the sets of potatoes, some cultivators recommend large sets, others small potatoes entire, and some large potatoes entire. Others, on the ground of experience, are equally strenuous in support of small cuttings, sprouts, shoots, or even only the eyes or buds. With all these different sorts of sets, good crops are stated to have been raised, though tolerable-sized cuttings of pretty large potatoes, with two or three good eyes or buds in each, are probably to be preferred.

5313. Independently of the increased expense of the seed, it is never a good practice to make use of whole potatoes as sets. The best cultivators in Ireland and Scotland invariably cut the largest and best potatoes into sets, rejecting, in the case of kidney potatoes, the root or meal end having no bud, and the top or watery end having too many. No objection is made to six or even three buds on each set, though one is considered sufficient. A very slight exercise of common sense might have saved the advocates for shoots, scooped out eyes, &c.; i.e., their experiments and arguments; yet Brown has observed, that the practical knowledge of the nature of the stems at the outset depends in direct proportion upon the vigour and power of the set. The set, therefore, ought to be large, rather smaller than the fourth part of the potato; and if the potato is of small size, one half of it may be practically used: at all events, rather err in giving over-large sets, than in making them too small. The first error can be sustained; whereas, by the other, a feeble and late crop may be the consequence. It is ascertained beyond doubt in Lancashire, Cheshire, and other counties in the north and west of England, that sets taken from the top or watery end of the potato, planted at the same time as others, will ripen first, and at a former end, whereas the contrary has been maintained also, and accounted for on the same general principle, that the plants raised from unripe tubers are both vigorous and more early than as are raised from tubers perfectly ripe. (See Gard. Mag., vol. III.)

5314. Sets should always be cut some days before planting; that the wounds may dry up; but no harm will result from performing this operation several weeks or months beforehand, provided the sets are not too much to the drought so as to deprive them of their natural moisture.
5315. The quantity of sets depends on the size of the potatoes; in general, where the sets are sufficiently large, from eight to ten cwt. will be required for an acre; more than ten for yams, and fewer than eight cwt. for the early nonsuch and ash-leaved.

5316. The modes of planting the potato are various.

5317. Where spade culture is employed, they are very frequently planted on beds (provincially lazy-beds), of four or five feet in width, with a trench 5 to 3 inches, or a shallow soil for earthing up the potatoes. This is the roughest mode of planting and cultivating potatoes, and unworthy of being imitated either on a farm or in a garden. The next mode is planting on a plain surface, either with or without manure, according to the state of the soil. Here the sets are placed in rows one foot apart, from eight to ten inches to two feet or more, and of any kind of potato, and from four to nine inches in the rows. In planting, a hole for each set is made by a man with a spade, while a woman or boy drops the set, and the earth is replaced; or the potato dibber is used, and the ground is trodden hard. Another kind of planting is by the trench, in which the soil is inclined to be dry, is in some cases practised, which is, after the land has been brought into a proper condition by ploughing over twice or oftener and well harrowed, to spread the manure regularly over the whole surface; the sets being planted in every third furrow, and the dung with the fine earth turned upon them by the harrow the following day. In this mode the next furrow is also planted, with some sets, which has on experiment been fully shown to be injurious to the produce. Besides, from the whole of the surface of the ground being covered with dung, a considerably larger proportion must be requisite when deposited only in the drills, and of course the crop cannot be cultivated to advantage in that respect.

5318. In planting the potato on sand land, after it has been prepared by the use of a plough that just pares off the surface and deposits it in the furrow, it is advised by Somerville to place the sets upon the inverted soil, and cover them with the loose mould from below by means of a common plough; or the trench plough may be used with perhaps more advantage; but a better method is that of paring and harrowing. In some cases the practice is, however, to turn down the turf with or without manure, and then to plant the set by a dibble; a better improvement of the former practice is, however, the placing the sets on the sand land, as the same is the usual time when the land is practised in Lancashire, and in some districts in the north-east of Scotland. The farmer having carried the dung, and laid it on the field in heaps, at proper distances, the operation is performed by the manufacturers and people who reap this work, and is as follows:—About forty feet away from the ridges of the set, three feet wide, and from ten to fourteen inches deep, according to the depth and quality of the subsoil. That being done, a second trench of the same breadth is marked off, and the surface-soil, to the depth of six or eight inches, is thrown into the bottom of the former trench, over which a sufficient quantity of dung being laid, the potatoes are planted at the distance of eight or ten inches from each other, and then, as much earth is taken from the bottom of the second trench as is necessary for covering the potato sets, and making up the first trench to its former level. Thus the field being completely trenched, well manured, and kept thoroughly dry by repeated spadings, an abundant crop of potatoes, but must also be in high condition for receiving whatever kind of seed may be afterwards sown.

5319. The mode of planting potatoes practised by the best farmers of the northern districts, is in drills formed by the plough in the same manner as in preparing the land for turnips. The soil is laid up into ridges from twenty-seven to thirty inches broad, the manure is distributed between them, and on this manure the sets are placed from four to eight inches asunder: they are then covered by reversing the ridges.

5320. The planting of early potatoes is carried to a very high degree of perfection in Lancashire. It is stated in The Lancashire Agricultural Report, in respect to the raising of seed potatoes, that upon the same ground from which a crop has already been taken, the early seed-potatoes are in some places afterward planted; which, after being got up about November, are immediately cut up into sets, and preserved in oat husks or saw-dust, where they remain till March, when they are planted, after having had one sprout taken off, which is also planted. The sprouts are of a length sufficient to appear above ground in the spring. In the most approved method, to cut the sets, and put them on a room-door, where a strong current of air can be introduced at pleasure, the sets laid thinner, as about two layers in depth, and covered with the like materials (chaff or saw-dust) about two inches thick: this screens them from the winter frosts, and keeps them moderately warm, causing them to vegetate; but at the same time admit of air to strike them, which is essential to the strength and size of the potato sets when planted, and thereby procure a good air and window opportunity afforded by mild soft weather. They frequently examine them; and when the shoots are sprung an inch and a half, or two inches, they carefully remove one half of their circumference, or with a wooden rake, taking care not to disturb the hands, or any loose earth, which was left in the set, so as not to injure the shoot with the fingers or kidney; from this sort, upon the same ground, have been raised four crops, having sets from the repository ready to put in as soon as the others were taken up; and a fifth crop is sometimes raised from the same lands, the same year, of transplanted winter lettuce. The first crop had the advantage of a covering in frost, which it is remarked that the useful information was communicated by J. Blundell, Grimskirk, and has hitherto been known only among a very few farmers.

5321. In the western parts of Lancashire the early potato is cultivated in the fields in warm situations, and in the districts marked on the map of Lancashire and the adjoining parts of Cheshire, the land being narrow and short. They are the lady’s finger, or early Rufford kidney, and the early round potato. The cultivators, aware that the buds from the root and top end of the tuber germinate at different periods, assort their sets in the following manner: 

748. a.

b. a.

c. b.

d. a.

After the drills are formed (fig. 748. a), loose earth is brushed with a spade or harrowed down, to the depth of six inches, in the interval between them (b); during the spring shoots begin to appear. The shoots on this cover have grown for about ten inches (c); the potato sets of the earliest degree (fig. 747. a) are then laid on the manure and mulch, at four or five inches apart, for the early crop; and sets of the second degree (fig. 747. b), at from six to eight inches apart, for later crops; and so on. The sets for the early crop are then covered with a spade, to the depth of two inches and subsequently covered, at two or three different times, to the depth of about five inches. The second and third crops are usually covered with the plough.
Some lay the potatoes intended for plants early in the year, before they are wanted to be cut, loose and separate in straw, or on warm, bearded clover, and then on flakes or frames, in warm situations near the fire, for the same purpose, in order that they may sprout; and when so sprouted to the length of half an inch or an inch, they are then carefully cut as described, assorted, and planted. (Gard. Mag. vol. i. p. 407.)

5525. In the north of Lancashire the potatoes are removed from their winter quarters in the last week of January, and spread out on a floor or placed on shelves in a room where a fire is kept, or in an upper room of a warm house. On the 56 of February they are covered with a blanket or thick cloth for about four weeks, which is then taken off in order to harden the sprouts. Towards the latter end of March the sprouts will be found about two inches long, and, if they are carefully set, the potatoes will be ready in a little over a month to bring the sets forward by spreading them out and slightly covering them with light mould under the stage or on the shelves of a greenhouse, or in a cucumber frame, or in a loft over a stable or cow-house. (Gard. Mag. vol. ii. p. 48.)

5526. In Denbighshire the early potatoes cultivated are the Foxley, the Nelson, and the Rufford kidney. Potatoes intended for sets the following year are taken up before they are ripe, just when the outer skin peels off, and before the stalks or stem have been formed within them; they are then cut into slivers or flakes, dried, and the thin outer skin, or surface fully exposed to the sun; they remain in that situation for a month or six weeks, when they become quite green and soft, as if roasted, and often much shrivelled; they are then put away in a cellar or pit, where they will remain dry, and neither invaded by frost nor much heat. In February they are examined, and every eye being then generally found full of long sprouts, they are fit to be planted. The tubers are therefore cut, seldom into more than two sets, viz. the eye or top part, which is planted by itself, and found to come a fortnight earlier; and the root or bottom part, which succeed them. (Gard. Mag. vol. ii. p. 172.)

5527. In gardens in the south of England potatoes are planted in a warm border from the first week of October, till the latter end of November. They are placed nine or ten inches under the surface, and well covered with dung. About the middle of March they are put in the field, and the ground is deeply hatted with a mattock, and made very loose about the plants; then in a fortnight or three weeks move the surface again, but the plants need not be earthed up unless they are very much exposed to the wind; when a little may be drawn about them to keep them steady. By this means an ash-leaved kidney potato may be gathered by the 15th or 16th of May, even in situations not favourable for early crops, and nearly three weeks earlier than they can be gathered from sets planted in the same situation in the latter end of February; and if ordinary care is taken in planting, no danger need be apprehended from the frost. (Gard. Mag. vol. vi. p. 67.)

5528. The latter kind of potatoes may be adopted in a field, more especially as ground that is to be used for potatoes in next year, and it is always better to plant potatoes in deeper thin, or even in a slightly more earthy, state than usual: the same the first, or to plant for the first time, the latter manner is adopted, the earth is thrown up from the intervening trenches. The hoe is generally used by market-gardeners.

The after culture, where potatoes are planted in ridges, as above described (5519.), commences when the plants begin to rise above the surface. They are then harrowed across, and afterwards the horse hoe, or small hoeing plough, and the hand-hoe are repeatedly employed in the intervals, and between the ploughs, as long as the progress of the crop will permit, or the state of the soil may require. The earth is then gathered once, or oftener, from the middle of the intervals towards the roots of the plants, after which any weeds that may be left must be drawn out by hand; for when the radishes have extended far in search of food, and the young roots begin to form, neither the horse nor hand-hoe can be admitted without injury.

5530. The after-culture adopted in some parts of Devonshire is somewhat singular, and deserves to be noticed. The sets are there generally cut with three eyes, and deposited at the depth of three inches with the spade or dibber: when the first shoot is three inches high, prepare a horse hoe with a broad head and flat or wave the middle and narrow the end, and move from the middle of the intervals towards the roots of the plants, after which any weeds that may be left must be drawn out by hand; for when the radishes have extended far in search of food, and the young roots begin to form, neither the horse nor hand-hoe can be admitted without injury.
5531. The culture of potatoes in the district of Kincardine is thus given by an intelligent writer in the Transactions of the Highland Society.

5532. The land is generally ploughed as early in spring as possible; and, that at least twice. In cases where the two ploughings do not sufficiently pulverize the ground, it re-ovens a third, and after every ploughing is well harrowed. The greatest attention ought always to be given to these preparatory operations.

5533. The ground being now prepared, and the season for planting arrived, drills are made for receiving the seed with the common plough; these are drawn about two feet broader, and three inches in depth. The first seven or them are all drawn from one end of the field, the harrow being returned out of the way, and then the other end, in order to allow time and room for the operation of putting in the seed, and also the dung, where this last operation is rendered necessary. By the time the ploughman has drawn three of these shallow drills or furrows, the persons in charge of the seed begin to plant the first of them, laying each plant at a distance of from nine to ten inches; these drills are four to five inches in depth of it, in the case already mentioned, where the manure is to be put into the drill. The ploughman, having completed seven of these drills, may now proceed to return, by ploughing to the depth of seven inches between the first and second drills, so as to leave the seed to be covered by the soil over the shallow drills of three inches, at the distance of two feet, as before mentioned, from the last which he had made, being the seventh; and returning back, he makes another of the seven inch deep furrows between the second and third rows of seed, which covers the second; returning, he opens another seed drill, and when he has returned back again a deep drill, between the third and fourth rows of seed, which covers the third, and so on from each end of the field. In this manner the drilling and planting will proceed, without any interruption or interference the one with the other, the plough having at first attained a sufficient distance from the planters to have always a drill open before they can overtake it. The great advantage of placing the seed so much nearer the surface than the deeper furrow alongside of it, is that it is more effectually protected from the bad effects of wet or damp, consequently less liable to be injured by frost, and it springs sooner.

5534. In this state the field is allowed to remain from a fortnight to three weeks, when it is cross harrowed to a perfect level. Afterwards, as soon as the drills can be distinguished by the potatoes shooting above the ground, the plough is again applied, and the drills are formed as before; but in doing so, the plough is taken as close as possible to the plant upon both sides, and upon the put in the other. The plough is raised, and the soil thrown over its side, from the front of the seed, so as to form the furrow which the plough had previously left at it, and forming at the same time a ridge, as it was originally, on the top of the plant. What is thus ploughed in the forenoon is cross harrowed that afternoon. The great advantage is to be derived from this process is the loosening of the soil, destroying the weeds, and the saving of hand-hoeing. I am satisfied, from my own particular experience and observation, that this mode of treating the young growth of the potato is far preferable to any other we have seen. It has been practised, but not to the same extent as given to the young plant may appear to one inexperienced in this particular mode of cultivating it.

5535. As soon as the weeds begin to appear, the plough is again introduced, which, in the opinion of this writer, is called "taking from the potatoes," which is done by running pretty close to the plant on both sides, so that a slight ridge is thrown up between the line of plants; and in this situation they remain for eight days, when the plant is "put to" by again applying the plough between the rows, and separating the earth composing the middle ridge above mentioned, towards the plant on each side. Without further treatment, the vacuum which the plough had previously left at it, and forming at the same time a ridge, as it was originally, on the top of the plant. But when it is thus ploughed in the forenoon is cross harrowed that afternoon. The great advantage is to be derived from this process is the loosening of the soil, destroying the weeds, and the saving of hand-hoeing. I am satisfied, from my own particular experience and observation, that this mode of treating the young growth of the potato is far preferable to any other we have seen. It has been practised, but not to the same extent as given to the young plant may appear to one inexperienced in this particular mode of cultivating it.

5536. The field culture of the potato in Argyllshire is thus given by an experienced cultivator in the Gardener's Magazine. He mentions sometimes applied to the field during winter and ploughed in, or it is by the better economists reserved till the field is drilled for planting. When the first plan is adopted, another ploughing is given across the field, which is then planted, the plough going one board along the furrow of which the set is placed, and then covered by the return of the drill. The best way is to go the dune, or drill, and the set on it (fig. 749 a, b, c, d, e), and then cover them up by clearing down the ridge, and forming others (b): a fortnight or so afterwards, the whole furrow is washed across (e), so that the plants have so far sprouted as that the drill can safely be traced from end to end (d), then the whole field is drilled over again with a very thin seed, and then the harrows are set immediately to work after the plough has finished drilling, and the field is levelled again (f). Any one that is unacquainted with the system would suppose the crop ruined, but it is not, as otherwise. The after-culture is no way different from the common practice of paring away the earth, drill harrowed afterwards, the drill being used up, as in other crops. It is advisable only to pare or earth, as the case may be, one side of the drill at each turn; as, by this means, the operations are sooner performed at the time, the earth is more thoroughly stirred, and at the same time to save the expense. The charm of this system consists in the additional drilling up and harrowing down; by this harrowing, the tyres or plough clods are turned to the furrow, where they are fully pulverised by the drill harrow and after culture, and all the weeds are so effectually drawn from between the plants that there is no use of hand-hoeing. The expense may be calculated at less than a third of hand-hoeing, from the effect and expediency; of course, dry weather is the more favourable for the hoeing and cross-harrowing to be performed. (Gard. Mag. vol. ii. p. 316.)
per acre of additional tubers will be produced. The experiments are related in the second volume of *The Horticultural Transactions*, and the practice is similar to one common among the growers of bulbous roots in Holland, as alluded to by Dr. Darwin, who also recommends its application to the potato. A woman or boy will crop the blossoms from an acre of potatoes in a day, or even in less time, when the crop is not excessively luxuriant.

5338. *The taking of the crop of potatoes* on a small scale is generally performed with the spade or three-pronged fork; but under judicious farm management, and the row culture, by the common plough.

5339. *The coulter is removed* and the plough goes first along one side of all the ridges of a ridge, or an end, and then these are brought together with the potatoes as exposed by proper distances, it returns and goes along the other side. When the land is somewhat moist, or of a tenacious quality, the furrow-slice does not give out the roots freely, and a harrow which follows the plough is commonly employed to break it and separate them from the mould. Various contrivances have been made for the purpose; for instance, a harrow with a guard placed in front of the plough, has been found to answer the purpose well, and to effect a considerable saving of labour. A machine for taking up and collecting potatoes is said to have been invented by Mr. Michael Barry of Snowdon in 1841, but though we have written to that gentleman, we have been unable to procure a description or drawing of his invention.

5340. A mode of *taking part of a crop* suited to cottagers and others, especially in years of scarcity, deserves to be mentioned. Having ascertained that some of the tubers have attained a catable size, go along the rows, and loosen the soil with a blunt stick, taking two or three of the largest tubers from each and returning the earth carefully. By keeping the edge of the blunt spatula or spade perpendicular to the main stem of the plant, the flat side will be parallel to the radiating roots, by which means they will be comparatively little injured. By this means both an early supply, and the advantage of two crops, may be obtained; for the tubers which remain will increase in size, having now the nourishment destined to complete the growth of those removed.

5341. *Potatoes intended for seed* should be taken up a fortnight or three weeks before being fully ripe, for the sake of conserving the young plants or seedlings of early potatoes, and will be recurved in disposing of the diseases of this plant. The ill-shaped, small, bruised, or diseased tubers should be laid aside, and the finest and best dried in the sun, spread on a cellar or loof floor, and covered with ashes, or chaff of sufficient thickness. After they have been dried in this state for a week or ten days the persons in Ireland plant potatoes from which they intend to procure sets extremely late, namely, the first week in July. The produce consequently never attains the same degree of size or ripeness as that of an earlier planted crop.

5342. *Potatoes are stored and preserved* in houses, cellars, pits, pies, and camps. Whatever mode is adopted, it is essential that the tubers be perfectly dry, otherwise they are certain of rotting, and a few rotten potatoes will contaminate a whole mass.

5343. The *most effectual mode*, and that which is generally adopted, consists in putting them into close houses, and covering them well up with dry straw. In some parts of Scotland it is a common practice to dig pits in the potato-field, when the soil is dry and light, and, having covered them with straw, to pile potatoes on them, and then to throw dry straw over these and that cover them up with earth, so deep that no frosts can affect them. Another method, which is practised in England as well as Scotland, is to put them together in heaps, and cover them up with straw, in the manner of preserving turnips, with this addition, that the heaps are afterwards well covered with earth, and so closely packed together as to prevent the rain from falling through them. Farmers in Lancashire in the course of using them take up sort and separate their potatoes according to their sizes, and are particularly careful to throw aside all those that are spoilt before raising, or that are cut in the taking up. This is a very necessary and proper precaution although by no means generally attended to, as the crop must have a much better chance for keeping, than when diseased or cut potatoes are stored up with it. It is also of great advantage to have the work performed in a dry season, as the potatoes should keep well when taken up wet, or when placed in any sort of repository for keeping while in that state.

5344. *Potato pies*, as they are called, are recommended by Young as the best mode in which potatoes can be stored. A trench, one foot deep and six wide, is dug, and the earth cleanly shoved out, and laid on one side, and on the bottom of the trench is laid over them a bed of straw; then the trench is filled with earth up about three feet high, in the shape of a house roof. Straw is then carefully laid over them six or eight inches thick, and covered with earth a foot thick, neatly smoothed by flat strokes of the spade. In this method he never lost any by the severest frosts; but in cases of its freezing with uncommon severity, another coat of straw over all gives absolute security. These pies when opened should each be quite cleared, or they are liable to deprecation. To receive one at a time, besides also being at first filled for immediate use, he has a house that holds about 700 bushels, formed of posts from fir plantations with wattled sides, against which is laid a layer of straw, and against the earth an upper and eighteen inch blade of straw. The roof is composed of two tiers of boards, one being beneath them in deep pits and laying them upon the surface. Camps are of various sizes; being too frequently made in a long square form like a corn-rick, and of a size proportioned to the quantity to be laid up. It has, however, been found by experience, that when the quantity is large, they are the most convenient; but, for a small quantity, lying sometimes with a sauce of mud between them, experienced campers hold, that a camp should not be more than three feet wide; four feet are perhaps as wide as it can be made with propriety, proportioning the length to the quantity; or, if this is very large, forming a range of short ones by the side of each other. The usual depth is a foot. The bottom of the trench is dry; the earth and straw are heated; care being taken as in measuring them with a bushel. On each side of the roof long wheat straw is laid, neatly and evenly, as thatch; and over this the mould raised out of the trench is evenly spread; making the surface firm and smooth with the back of the rake. It is a good plan to spread over the whole of the roof, as a cover, as a guard against frost. It is needless to observe that a camp should have a dry situation; and that the roots ought to be deposited in dry as a state as possible. These camps are tapped at the end, some having, or a quantity of loose straw, being thrust close in the open end, as a bung of safeguard. It is evident that the object in the making of these large camps during the winter is to keep the potatoes for a long period. It has been suggested, that the best method yet discovered for keeping potatoes sound for the longest period, is to spread them on a dry floor early in the spring, and to rub off the eyes occasionally, as they appear to have a tendency to push out; but by using these precautions, Donaldson has frequently seen potatoes kept in good condition till the month of June.

5345. In Canada and Russia the potato is preserved in boxes in houses or cellars, heated when necessary to a temperature one or two degrees above the freezing point by stoves. (Farm Mag. vol. xx. p. 486.)
To keep potatoes any length of time, the most effectual way is to place them in thin layers on a platform suspended in an ice cellar. There the temperature being always below that of active vegetation, they will not sprout, while not being above one or two degrees, the discs will not be frost bitten. Another mode is to scoop out the eyes with a very small spoon, and keep the roots buried in earth. A third mode is to destroy the vital principle by kilndrying, steaming, or scalding. A fourth mode is to bury them so deep in dry soil that no change of temperature will reach them, and consequently, being without air, they will remain upwards of a year without ever tainting.

The produce of the potato varies from five to eight, and sometimes ten or twelve tons per acre; the greatest produce is from the yam, which has been known to produce twelve tons or 480 bushels per acre. The haulm is of no use but as manure, and is sometimes burned for that purpose, being slow of rottting.

The most important application of the potato crop is as human food; on this it is unnecessary to enlarge.

Endhoff found meanly potatoes to contain twenty-four per cent. of their weight of nutritive matter, and rye seventy per cent.; consequently, a half of potatoes-four and a half of rye-and using twelve measures of rye. A thousand parts of potato yielded to Sir H. Davy from 200 to 250 parts of nutritive matter, of which from 15 to 200 were mucilage or starch, fifteen to twenty sugar, and thirty to forty gluten. Now, supposing an acre of potatoes to weigh nine tons, and one of wheat one ton, with soil of about the usual proportion; then as 1000 parts of wheat afford 950 nutritive parts, and 1000 of potato say 50, the quantity of nutritive matter afforded by an acre of wheat and potatoes will be nearly as nine to four; so that an acre of potatoes will supply more than double the quantity of human food afforded by an acre of wheat. The potato is perhaps the only root grown in Britain which may be eaten every day in the year without satiating the palate, and the same thing can only be said of the West India yam and bread fruit. They are, therefore, the only substitute that can be used for bread with any degree of success; and indeed they often enter largely into the composition of meals without at all interfering with the true bread (Engy. art. Baking). In the answer by Dr. Tissot to M. Lanquet, the former objects to the constant use of potatoes as food, not because they are pernicious to the body, but because they hurt the faculties of the mind. He owns that those who eat maize, potatoes, or even millet, may grow fat and acquire a large size; but doubts if any sacred or literary work of merit. It does not, however, by any means appear that the very general use of potatoes in our country has at all impaired either the health of body or vigour of mind of its inhabitants.

The manufacture of potato flour is carried on to a considerable extent in the neighbourhood of Paris. This flour is sold at a price considerably higher than that of wheat, for the use of confectioners and for bakers who prepare the finer sorts of bread. The potatoes are washed and grated, and the starch separated from the pulp so obtained by filtration; it is dried on shelves in a room heated by a fire, and after a day or a floor roll by pressing the cake in a cast iron plate; the pulp is then put in a pressing machine and put up in sacks for sale. The most complete manufactory in the neighbourhood of Paris in 1829 was that of M. Delisle at Bondy. (Gard. Mag. vol. vi.) Most of the operations there are performed by a steam engine attended by children. It is reported that 850,000 tons of potatoes are annually manufactured into flour within a circle of eight leagues around that city.

The quantity of farina which potatoes produce varies not only according to the species, but according to the period at which the extractions are made. The variations produced by this last cause are nearly as follows:-Two hundred and forty pounds of potatoes produce of farina, or potato flour, in

The extraction of the farina should be discontinued at the period when the potatoes begin to grow, the farina being destroyed by germination. Red potatoes produce less quantity of farina than yellow or white, which are also of a better quality; the white, which is often tinged with red in the interior, is the best proper for this extraction. The best of all is that which has a yellow tint, as its farina is of very good quality, and abundant. (Higie de Bruxelles).

Potato flour is made into bread; it is a very simple matter. Its adhesive tendency does not admit of baking or kneading unmixed with meal or wheaten flour; but it may be made into cakes in the following manner:—A small wooden frame nearly square is laid on a flat pan like a frying-pan; this frame is grooved, and so constructed, that, by means of a long, narrow presser or lever, it is pressed into a paper of the mould. The frame containing the farina may be almost immediately withdrawn after the mould is formed upon the pan; because, from the consistency imparted to the incipient cake by the heat, it will speedily admit of being safely handled. It must not, however, be fried too hastily; otherwise it is apt to become unpleasantly hard and brittle for inscription. This precautionary measure being observed, it will be found, that, where thoroughly ready, the breadth of potato flour, even unaided by any foreign ingredient, will eat very palatable. It might thus, from time to time, be soaked for puddings, like the tapioca; or it might be used like the cassava-cake, which in appearance and quality it so much resembles; that is, when well buttered and toasted, it will make an excellent breakfast appendage. (Quart. Journ. Agr. vol ii. p. 53.)

The material for potato flour may be preserved for years closely packed in barrels, or unground in the form of peels, having been previously cooked in steam, as originally suggested by Forsyth, of Edinburgh. (Engy. Brit.) Some German philosophers have also proposed to freeze the potato, by which the feculent matter is separated from the starch, and the latter being then dried and compressed, may be preserved for any length of time, or exported with ease to any distance. (Annals des Sceliers, vol i. p. 500.)

The manufacture of tapioca from potatoes is thus given in the Quarterly Journal of Agriculture. The potatoes selected are thoroughly washed, and which they are grated in a machine constructed for the purpose. The chips thus produced fall into a Considered grater placed underneath. From this vessel they are removed, and strained into a tub. On the juice being well expressed for the first time, the fibrous matter is set apart, and cold clean water is thrown over them. These fibres are again put through the same or similar machine, and the whole of the substance is collected, which then being thoroughly dried is done, the contents of the tub, now in a state of muriculture or starch, are allowed to settle. A reasonable interval between stopping, the old water is poured gently off, and fresh water supplied. After this process of freezing and washing, the blanched matter is passed through a smaller strainer. The variations used is one of the finest texture, so that no improper or accidental admixture may interfere. As soon as the starch, thus purified, is firmly subsided, it is spread on a board, and exposed to the open air. The starch evaporates, on which it is, as a security for cleanliness, put through a sieve.
5368. **A large circular pan** is now procured, and set upon the fire. The farina is gradually put into the pan, till what is conceived to be sufficient for one cooking be supplied. As the natural tenacity of the farina, in a warm state, is to adhere to the pan, great care is requisite in constantly turning and stirring it. This is effectually done with a broad flat piece of wood, having a hollow handle; and it is removed from the heat. A temperature of 120° Fahrenheit suits best for perfecting the tapioca. When the farina becomes quite hard, dry, and gritty, it is then ready, and may be taken off the fire. (Quart. Journ. Agr. vol. ii, p. 88.)

5369. The **ordinary economical applications of the potato**, next to those of the culinary and baking arts, are in starch-making and the distillery. Starch is readily made from the scraped and washed tubers cut into small pieces and steeped in water; and a spirit is distilled from mashed potatoes, fermented so as to change a portion of the starch into sugar. In general it is found that three and a half bushels of potatoes affords the same quantity of spirit as one of malt.

*5369. Potash* may be extracted from potato leaves and stalks by the following process:—Cut off the stalks when the flowers begin to fall, as that is the period of their greatest vigour; leave them on the ground eight or ten days to dry, cart them to a hole dug in the earth about five feet square and two feet deep, and then burn them, keeping the ashes red-hot as long as possible. Afterwards take out the ashes, pour boiling water on them, and then evaporate the water. "There remains after the evaporation a dry saltpetre-like substance, known in commerce under the name of crude saltpetre, which is of a very greyer, and the more valuable the *satin* becomes. The *satin* must be calcined in a very hot oven, until the whole mass presents a uniform reddish brown. In cooling it remains dry, and in fragments bluish within, and white on the surface; in which state it takes the name of potash." (Smith's Mechanic, vol. ii. p. 381.)

5361. Among extraordinary applications of the potato, may be mentioned cleaning woolens, and making wine and ardent spirit.

5362. Cleaning woolens. The refuse of potatoes used in making starch when taken from the sieve, possesses the property of cleansing woolen cloths, without hurting their colour; and the water decanted from the starch powder is excellent for cleansing silks, without the smallest injury to the colour.

5363. Wine, of a good quality, may be made from frosted potatoes, but not so much as to have become soft and watery. The potatoes must be crushed or bruised with a mallet, or put into a cider press. A bushel must have ten gallons of water, prepared by boiling it, mixed with half a pound of hops, and half a pound of common white ginger. This water, after having cooled for an hour, must be poured upon the bruised potatoes, into a tub or vessel suited to the quantity to be made. After standing in this mixed state for three days, yeast must be added to ferment the liquor. When the fermentation has subsided, the liquor must be drawn off, as fine as possible, into a cask, adding half a pound of raw sugar for every gallon. After it has remained in the cask for the space of six weeks, it will not then be safe to open. (Smith's Mechanic, vol. ii. p. 325.)

*5365. In the application of potatoes as food for live stock, they are often joined with hay, straw, chaff, and other similar matters, and have been found useful in many cases, especially in the later winter months, as food for horses, cows, and other sorts of live stock. With these substances, and in combination with others, as bean or barley-meal and polard, they are used in the fattening of neat cattle, sheep, and hogs.

5366. Potatoes are much more nutritive when boiled; they were formerly cooked in this way, but are now very generally steamed, especially in the north. The practice has been carried to the greatest extent by Curwen in feeding horses. He gives to each horse, daily, a 750

5367. Machines for washing potatoes are numerous, and in addition to that already described, we shall here notice two other forms. One of the simplest is a trough [fig. 260, a, b] containing a hollow cylinder (c) with a handle (d), which is made fast to the axis which passes through the cylinder. A number of the spares which run longitudinally are so constructed as to form a kind of door, which is made fast by two line-pins at each end of the cylinder. The vessel is filled with water, charged with potatoes, the trough filled with water, all that is necessary for the purpose of cleaning is only to turn the cylinder. The machine then turns the spares are washed in an hour by Mr. John Lawson, of Elgin, consists of a wooden or iron trough, with a movable bottom above the fixed one, composed of spares three quarters of an inch apart. The potatoes are laid over the movable ribbed bottom, and water being admitted at the top and led off by a cock, they are sent backwards and forwards by a wooden hoe, till they are clean, when the dirty water which has collected between the two bottoms is let off by another cock at the opposite end. (Brit. Farm. Mag. vol. ii.)

5368. The boiling of potatoes, though a simple operation, is in many districts not performed in the best manner. The following is the Lancashire method:—Set them on the fire in cold water; when boiled, pour the water over them completely, add a little salt, and dry them well at the fire. Another method: Choose four potatoes of equal size, and put them into a saucepan, or pot without a lid, with no more water than is sufficient to cover them; more would only spoil them, as the potatoes themselves being on boil, yield a considerable portion of water. By being boiled in a vessel without a lid, they do not trickle, and all waste
Part III.

PRACTICE OF AGRICULTURE.

5369. Frosted potatoes may be applied to various useful purposes, for food by thawing in cold water, or being pared, then thawed, and boiled with a little salt. Salt, or salt-petre, chaff, or bruised oats, boiled with them, will render them fit food for cattle, swine, poultry, &c. Starch, and paste for weavers, bookbinders, and shoemakers, may be made from them when too sweet to be rendered palatable, and also an ardent spirit, from hydrometer proof to 10 per cent over proof.

5370. The diseases of the potato are chiefly the scab, the worm, and curl.

5371. The scab, or ulcerated surface of the tubers, has never been satisfactorily accounted for; some attributing it to the ammonia of horse-dung, others to alkali, and some to the use of coal ashes. Change of soil, and of seed, and of the potato variety grown at present, is the only resource known to prevent this disease, and the same preventive is recommended. The only serious disease of the potato is the curl, and this is now ascertained to be produced by the too great concentration of the sap in the tubers; and this concentration, or thickening, is prevented by throwing the tubers into cold water. The farmer who observes that seed potatoes procured from the moors, or elevated cold ground, in the internal parts of the country, never suffered from the curl, and it consequently became a practice, every three or four years, to procure a change of seed from these districts. On enquiry, it was found, that the potatoes in these upland grounds continued in a growing state till the haulm was thinned by the first frosts of October. They were then taken up, when, of course, they could not be ripe. Subsequent experiments, which will be found detailed in The Farmer's Magazine, and Caledonian and London Horticultural Transactions, have fully established the fact, that the curl is prevented by this means. The farmer ought to select his seed stock a fortnight or three weeks before he takes up the general crop, as already recommended. It is also a safe practice frequently to change the seed, and also to change the variety.

5372. Shirreff, an ingenious Speculative, and practical agriculturist, is of opinion that there are only two causes for the curled disorder in potatoes. The first is excessive seed-bearing, that is, carrying great quantities of plums or apples; from the effects of which, if the plant be not too far advanced in life, it may recover for a time, by removing it to a shady or upland situation. The second cause is the soil being too cold and sterile: that is, ultimately to the curving of the curling, followed by death, on the whole animal and vegetable kingdoms. An old decaying oak is an instance of the curled or shrivelled state of trees from age, as is the lean and slippered pantaloons of the curdled disorder from old age in the human species.

5373. The turnip is a native of Britain, but in its wild state it is not to be recognised by ordinary observers from wild mustard. It was cultivated as food for cattle by the Romans; and has been sown for the same purpose in the fields of Germany and the Low Countries from time immemorial.

5374. When they were introduced in this country, as a field plant, is unknown: but it is probable turnips would be found in some gardens of current before the middle of the seventeenth century, though then, and for a long time after, in a very inferior and ineffectuall manner. It has been stated that turnips were introduced from Hanover in George I's time; but so far from this having been the case, George II. caused an abstract of the turnip book to be drawn up for his use, which appears in William's Polyt. Survey, &c. vol. iii. p. 80. The introduction of improved turnip culture into the husbandry of Britain, Brown observes, "occurred of those revolutions in rural art which are constantly occurring among husbandmen; and, though the revolution came on in an irregular and accidental manner, it was viewed as completely and thoroughly established. Before the introduction of this root, it was impossible to cultivate light soils successfully, or to devise suitable rotations for cropping them with advantage. It was likewise a difficult task to support live-stock through the winter and spring months; and as for feeding and preparing cattle food, the market during these inclement seasons, the practice was rarely thought of, and still more rarely attempted, unless where a full stock of hay was provided, which only happened in very few instances. The benefits derived from turnip husbandry are, therefore, of great magnitude. Light soils are now cultivated with profit and facility; abundance of food is provided for man and beast; the earth is turned; and where the earth is turned, and the crops are well broken, there is a great use for which it is physically calculated; and, by being suitably cleared with this preparatory crop, a bed is provided for grass seeds, wherein they flourish and prosper with greater vigour than after any other preparation." (Treatise on Rural Affairs.)

5375. Turnips and clover, it is elsewhere observed, are the two main pillars of the best courses of British husbandry; they have contributed more to preserve and augment the fertility of the soil for producing grain, to enlarge and improve our breeds of cattle and sheep, and to afford a regular supply of butcher's meat all the year, than any other crops; and they will probably be long found vastly superior, for extensive cultivation, to any of the rivals which have often been opposed to them in particular situations. Though turnips were long cultivated in Norfolk before they were known in the northern counties, yet it is an undoubted fact that their culture was first brought to perfection in Roxburghshire, Berwicke-shire, and Northumberland, and chiefly through the exertions of Dawson, of Froglen, in the first named county, and of Culley, in the latter.

5376. Drilling turnips, as well as other crops, evidently originated with Tull, whose first work, Specimen of a Work on Horse-breeding, appeared in 1751. It appears that Craig, of Armathwaite, in Cumberland, began to drill turnips about 1745; and next we find Philip Howard, of Corby, drilling in 1755; and Pringle, drilling "from hints taken from Tull's book," in 1756 or 1757. William Dawson, who was well acquainted with the turnip culture in England, having been purposely sent to reside in those districts
for six or seven years, where the best cultivation was pursued, with an intention not only of seeing, but of making high crops, and of their main properties, the advantage of the superiority of Pringle's mode over every other he had seen, either in Norfolk or elsewhere; and in 1702, when he entered on Frogmore Farm, near Kelso, in Roxburghshire, he immediately adopted the practice upon a large scale, to the amount of 100 acres yearly. Though none of Pringle's neighbours followed the example, yet no sooner did Dawson, an actual or rent-paying farmer, adopt the same system, than it was immediately followed by several farmers in his vicinity, but by those very farmers adjoining Pringle, whose crops they had seen, for ten or twelve years, so much superior to their own: the practice rose to be general. Drilling turnips was first introduced to the county of Northumberland, about the year 1780.

*5577. The varieties of turnip grown by farmers may be arranged as whites and yellows.

5578. Of white turnips, by far the best and most generally cultivated is the globe; but there are also the green-topped, having the bulb tinged greenish; and purple-topped, with the bulb reddish: which, though they do not produce so large a crop as the globe or oval, stand the winter better, and the red-topped, it is said, are more tender. The small bulb, or turnip, has a white bulb which rises from eight to twelve inches high, standing almost wholly above ground. It is less nutritious than any of the others, and more liable to be attacked by frost.

5579. Of yellow turnips, there are the field or Aberdeen yellow, which is more hardy than the globe, and answers well for succeeding that variety in spring; and the rutabaga, or Swedish turnip, which may be preserved for consumption till June. The Siberian turnip has a bulb and a branchy top, but both of inferior quality. It is a hybrid between a white rutabaga and field cabbage, or between rape and cabbage.

5580. New varieties are obtained by selection and by counter impregnation; but in either case the greatest care is requisite to keep the plants at least a full growing from any other of the brassica tribe likely to flower at the same time, otherwise the progeny will certainly be hybridised.

5581. The choice of soils may be considered as limited to the white, globe, yellow, and Swedish, according as early, middling, or late supplies are wanted. No other varieties are grown by the best farmers.

5582. In the choice of seed the farmer must rely on the integrity of the seed-dealer, as it is impossible to discover from the grains whether they will turn out true to their kinds.

5583. Turnip-seed requires to be frequently changed; and the best is generally procured from Norfolk and Northumberland. The Norfolk seed, Forsyth observes, is sent to most parts of the kingdom, and even to Ireland; but after two years it degenerates; so that those who wish to have turnips in perfection should procure it fresh every year from Norwich, and they will find their account in so doing: for, from its known reputation, many of the London seedsmen sell, under that character, seed raised in the vicinity of the metropolis, which is much inferior in quality.

5584. Turnip-seed of any age will grow, if it has been carefully preserved; that which is new, comes up first, and therefore it is not a bad plan to mix new and old together, as a means of securing a braid against drought or the fly. Whether plants from new or old seed are most secure from the depredations of the fly, is perhaps a question which cannot be easily determined, even by experiments; for consequent circumstances are so many, and powerful, to render the difference between them, if there be any, imperceptible. It is, however, known to every practical man, that new seed vegetates several days before the old, and more vigorously; and it is equally well known that the healthy and vigorous plants escape the fly, when the stunted and sickly seldom or never escape it. Hence it would seem, that new seed, Brassica paria, is more secure from the fly than old.

5585. The soil for turnips should always be of a light description. In favourable seasons very good crops may be raised on any soil; but from the difficulty of removing them, and the injury which the soil must sustain either in that operation, or in eating them on the spot with sheep, they never on such soils can be considered as beneficial to the farmer. Turnips cannot be advantageously cultivated on wet tenacious soils, but are grown on all comparatively dry soils under all the variations of our climate. On dry loams, and all soils of a loose texture, managed according to the best courses of cropping, they enter into the rotation to the extent of a fourth, a sixth, or an eighth part of the land in tillage; and even on clayey soils they are frequently cultivated, though on a smaller scale, to be eaten by cattle, for the purpose of augmenting and enriching the manure, into which the straw of corn is converted.

5586. The climate most desirable for the turnip is cool and temperate. This was long ago noticed by Pliny, and it is so obvious on the Continent that it admits of no dispute. Von Thaer observes that the turnips grown on the fields of Germany seldom exceed half a pound in weight, and that all his care could not raise one beyond fourteen pounds. In France and Italy they are still less. A rapid climate is equally disadvantageous to the turnip; and they are accordingly found of no size in Russia, Sweden, and many parts of North America. Even turnips grown in the southern counties of England, in the same excellent manner as in Northumberland, never equal the size of those grown in the latter county, or further north, or in Ireland.

5587. The field culture of turnips is effected either by sowing the seed of the plant from the hand on a flat surface, or by depositing it on the tops of little ridges. In the best cultivated districts, the latter method is universally practised and approved of, chiefly for these reasons:—1. By this method the land may be more easily and perfectly cleaned during the growth of the plants; the width of the rows affording the means of better tilling the intervals. 2. The plants can be more cheaply and quickly hand-hoed, the process being so simple as to be taught to young persons in a few hours, whereas when the plants are not regularly disposed in rows, a considerable degree of experience and time are requisite. 3. The manure may be more perfectly covered, and by being applied in a more effectual manner to the roots of the plants, a smaller quantity will suffice. And lastly, the turnips may be kept drier, and crops of them in conse-
quence raised on land so wet as otherwise to be incapable of yielding a return of any value. We shall give their culture from an excellent paper in the Quarterly Journal of Agriculture, vol. i., from which also this paragraph is quoted.

5388. Preparation of the land. The land intended for the turnip crop is ploughed in autumn, after the preceding crop of grain has been reaped. If the soil be not of a very dry nature, the land is formed into ridges of fifteen feet or more, and care is taken that no water shall stagnate on the ground. In this condition the land remains during the winter; and it is ploughed again in spring as soon as the ground is sufficiently dry for that purpose, and as soon as the other labour of the farm will allow; this second ploughing is generally made in a direction to cross the previous one. The land is then repeatedly grubbed and harrowed in various directions, for the purpose of pulverizing the mass of dragging to the surface, and disengaging all weeds and roots; to assist in which process the aid of the roller is frequently requisite; the roots and weeds disengaged are then gathered with care, and either burnt in little heaps on the ground, or removed away to a larger heap, to be mixed with quick-lime and other substances to form manures, or to form aids for manuring the crop for the succeeding year; at the same time such stones as impede the plough may be removed; after this the land is again ploughed, and generally, as before, in a direction crossing the last furrows; and the same process of harrowing, rolling, and collecting the disengaged weeds, is repeated. The earth is once more ploughed, and again the same operations are repeated; and after the land is usually in a fit state to be formed into ridges or drills. Should this not be so, the operations of ploughing, harrowing, and gathering of weeds must be repeated, and that until the land is cleared of all injurious roots, and reduced to a loose or friable state. The perfect preparation of the land in this stage of its culture, is of very great importance to the future crop.

5389. Forming the ridges. After the preparation described, the land is formed into little ridges or ridgelets, either by the common plough, or by a plough with two mould-boards, formed for that purpose. The first of these is to be preferred when the method of performing the work is once pointed out in the field. The ridges are formed with a sharp top, as a transverse section (fig. 751) will show. The distance of these ridgelets may be from twenty-seven to thirty inches, measuring from top to top. This interval is necessary to allow of the horse-hoe filling the intervals, in the manner to be afterwards described, and to admit a sufficient circulation of air between the rows of plants.

5390. Manner of applying the manure. The chief manure applied to this crop is farmyard dung, or that which is produced by the consumption of the straw and other produce of the farm. This manure ought to be well rotted, and so that end either turned over in the court-yard some weeks previously to its being used, or carried out in winter to the fields intended for the turnips, and there laid in one or more large heaps. If the carts are not suffered to go upon these heaps, the putrefactive process will proceed with greater quickness. When the ridgelets are formed in the manner described, the dung is filled into carts drawn by one horse, and transported quickly to the land. The manner of applying it is this:—The horse with the loaded cart walks in the interval of the ridges, so that a wheel of the cart shall go in each of the hollows of the two ridges adjoining. The person who directs the horse follows the cart, which is open behind, and with a crooked two-pronged fork or dung-hack, (fig. 752,) drags out the dung, as the horse moves along, into little heaps in the hollow of every third ridge, at the distance from each other of eight to ten feet. For two-pronged or three-pronged fork (fig. 753,), each walking in the interval of a ridge, and spreading out the dung in as regular a manner as possible; as a transverse section of the ridgelets with the dung deposited in the intervals would show (fig. 754.)

5391. Covering the dung. The dung is no sooner spread in this manner than it is covered by the plough. To this end is employed either the common plough, or that with the double mould-board already mentioned: these passing down the middle of each ridgelet split it into two, so that the ridgelet is divided into two ridges immediately above the former hollow of the old ridgelet, (fig. 755.) The dung is now completely covered, and a new ridge for the reception of the seed is at once formed. The double mould-board plough performs this operation at once, the common plough by going and returning up the middle of each ridge.

5392. Broad-cast dunging. Instead of depositing the manure in the manner described, it is sometimes laid upon the stubble after harvest, and then ploughed in. This is only practicable where there is a supply of manure remaining from the preceding year, or where it can be elsewhere procured; and is only admissible when the land is so clean as to require little preparation in the succeeding spring. As liberal an expenditure as can be afforded of manure is always expedient in the case of this crop, the goodness of which will much depend upon the fertility we are able to communicate to the soil. Ten or twelve tons per acre may be considered the regular manuring on a turnip-farm, where a proper rotation of crops is followed.

5393. Lime, sea-weed, ashes. Sometimes lime is applied to the turnip crop, together with dung. This may be done by laying the lime upon the stubble after harvest, or better still, by spreading it upon the ground, and harrowing it well immediately before the forming of the ridgelets for the reception of the dung. Putrescent manures, however, are considered superior to the calcareous for the production of this plant; and all of the former kind may be used with effect. Street dung is an exceedingly good manure; sea-weed will also be useful: this last, however, is not applied in the manner of the farmyard dung, but is carried off as it is cast on shore, laid on the surface, and suffered to remain so till the land is
ploughed. Ashes generally produce a good effect in causing the seeds to vegetate quickly, but the fertilising powers of some of these do not appear to be of a permanent nature. Bruised bones and various other substances have been used with much benefit; but it is to be observed, that putrescent matters form the main support of the turnip cultivator, and that the others are only to be regarded as subsidiary.

5394. Sowing the turnips. The land being formed into ridgelets in the manner described, is ready for the reception of the seed. This is sown on the tops of the ridgelets by machines of various forms.

5385. The most simple of these consists of a hollow cylinder of tin, fixed upon an axle, and moving round with two light wheels, distant from each other twenty-seven or thirty inches, which are made to run in the hollows of the ridges, (fig. 2688.) The seed is put into the cylinder through an aperture which opens and shuts for that purpose: this cylinder turning round with the axle, the seed drops, through small equidistant holes made in it, into a tin tube, by which it is conveyed to the ground. Immediately before this tube is a hollow coulter of iron, sharp before, which inclines the forerpart of the tin tube, and makes a track in the ground from one to two inches deep, into which the seed drops. This simple apparatus is mounted upon a light wooden frame-work, having two shafts behind, by which the workman holds and keeps it steady. The coulter is then attached by a rope to a light wooden roller, in the shafts of which the animal of draught is yoked. More perfect machines, however, may be employed where turnips are cultivated upon a large scale, and we may refer to that of French (1865.) as one of the best.

5396. The preparation of turnip-seed for sowing, by steeping in the drainings of dung-hills and other similar matters, has been recommended as a likely mode to prevent the fly; but it is not found to have this effect, and is never followed.

5397. The following mode of preparation is sometimes adopted:—Half new and half old seed are mixed together; then half is taken and steeped in water for three or four hours; afterwards both steeped and unsteeped seed are mixed and immediately sown. The object of this preparation is to obtain four different brands or risings of the seed, which are supposed to give four chances of escaping the fly that attacks the infant plants, instead of one. Another mode is to join radish seed to the above, new and old, steeped in the foregoing manner. It being found that the fly prefers the radish to the turnip. Some recommend the mixing of an equal quantity of rape-seed with the turnip-seed, alleging, that if a fly cuts off the turnips, the rape may be left for a crop; and that if the turnips escape, the rape may be treated as weeds. The most common precaution, however, as to the fly, is to sow thick, or to mix the seed with soot, lime, or ashes.

5398. The quantity of seed used may be from two pounds to two and a half pounds avoidadupose per acre. It is necessary to give a sufficient quantity of seed, to provide against the loss of plants from the ravages of insects, and other contingencies. But the quantity should not be excessive; because the plants, when too thick, get interwoven together, and thence become difficult to be thinned in a proper manner.

5399. The sowing process being completed, the ridgelets remain flattened and compressed. (fig. 756.)

5400. The several operations of forming the ridgelets, spreading the dung, covering it by the plough, and sowing the seed, ought to be carried on in close succession. The dung must be immediately covered, that none of its powers may be lost by evaporation; and the seed, to ensure its early vegetation, ought to be sown as soon as possible upon the moist earth turned up. The various works of the turnip culture, thus carried on at the same time, furnish the best specimen which the culture of the fields affords of the beneficial effects of a proper division of labour. The process has all the appearance and effects of garden culture, with the difference of its being conducted with incomparably greater economy and despatch.

5401. The period of sowing in the north of England and Scotland is from the 1st to the end of June, though it is often continued to the middle of July. The turnips, however, sown after the latter of these periods seldom attain to a proper size; and, when sown earlier than the 1st of June, they are apt to shoot forth the seed-stem before winter, by which not only the soil is deteriorated, but the nutritive juices of the root exhausted. In the south of England they may be sown somewhat later than in the north.

5402. The time of sowing in other countries must be varied by the nature of the climate and soil. It is to be inferred, that in warmer countries, where vegetation is more rapid, the sowing should be deferred till a later period. At Rouillé, in the north of France, M. de Dombasle sometimes sows in August, and yet obtains a medium crop.

5403. Hoeing. When the plants are an inch or more in height, or when weeds appear amongst them, the process of hoeing commences. This is done either by a small plough drawn by one horse, going and returning along the hollow of each ridgelet, and cutting of a slice of earth from the sides, as near to the turnips as possible (fig. 757.)

or by the horse-hoe, of which there are various kinds. The most simple of these consists of a flat triangular share (fig. 758. a), with two lateral arms (b, b.), formed to set wider or narrower, and fixed to a beam and handles by three upright coulters of iron; or, which is better, the lateral arms are omitted, the triangular share fixed to the beam, and two moveable upright coulters attached by a cross bar.
5404. One of the best turnip horse-hoes is formed from the skeleton of a common plough (fig. 759), by

![Diagram](image)

two coulters of iron curved inwards (a, b), and fixed to wooden bars (c, f, and e, d), which last again are hooked to the beam of the implement, and made, by means of a cross iron bar (g, h), to be set at a greater or smaller distance from each other as it may be required. A broad iron share (i) moves in the middle of the hollow of the ridges, while the two coulters on each side go as near to the rows of turnips as can be done with safety; and in this manner the intervals of the ridges are filled, and the weeds within them, and as near to the plants as the coulters can go, cut up and destroyed. By removing the wooden bar and coulters of this machine, and hooking it to, on each side, a small cast-iron mould-board, it is converted to the double mould-board plough also, as we have seen.

5405. The horse-hoes or horse-hoes of Wilkie (2697.), Finlayson (2667.), or of Kirkwood (4955.), may easily be set and arranged for this or any other description of culture; so that it requires no new implements.

5406. The hand-hoers go to work, each having a little iron hoe, fixed upon a wooden handle about three feet in length (fig. 760). The breadth of the blade (a) of this hoe is eight inches; and the workers, standing in the hollow with their faces to the ridges, hoe the turnip plants, leaving them standing singly, at the distance from each other of from ten to twelve inches. By this operation the rows of the turnips are cleaned of all weeds; the superfluous plants cut up and pushed into the intervals, where they die; and the plants to be preserved left standing singly at the distance required. A transverse section of the ridges will then appear thus (fig. 761), and

![Diagram](image)
a longitudinal section thus: (fig. 762.) The plants should not be nearer to each other than ten inches, that they may increase to a proper size.

5407. Second horse-hoeing. Soon after the operation in question, weeds will again sprout up in the intervals of the ridges and amongst the plants. In the course, therefore, of twelve days or more the horse-hoe again passes through the intervals of the ridges, cutting up all the weeds that may have sprung up; and soon after the hand-hoers again go to work with the same instrument as before, cutting up all weeds which may have grown amongst the turnips, and carefully singling any plants that may by chance have been omitted in the first hoeing. After this process, a section of the ridges will appear thus: (fig. 763.)

![Diagram](image)

5408. Third horse-hoeing. Sometimes the horse-hoe passes once more down the intervals after a short period; but more generally the previous hand-hoeing concludes the process upon all the drier lands, the weeds being now kept down by the rapid growth of the plant, and the overshadowing of the intervals by its leaves. Very commonly, however, at an interval of eight or ten days after the last hand or horse-hoeing, the earth which had been taken from the roots of the plants by these several hoerings is again laid back, either by the little one-horse plough already mentioned, or by the double mould-board plough, passing down the intervals of the rows and ridging up the earth thus: (fig. 764.) The design in this operation is, that any weeds remaining in the intervals after the former hoerings may be destroyed, and that the land and turnips may be kept more dry during wet weather and the months of winter. This concludes the culture of the turnip, which now grows rapidly without further care; and by the beginning of September the leaves of a good crop will have covered the entire surface, making a transverse section of the ridges appear thus: (fig. 765.)

![Diagram](image)

5409. The Swedish turnip is cultivated, used, and stored precisely in the same manner as the common turnip; but it is generally sown several weeks earlier. It does not attain to the same weight by the acre; and, as it is more difficult to raise, it ought to receive a greater quantity of manure, and to be always upon good land. The Swedish has a property which the common turnip has not, that of being to be transplanted
when young; so that, where blanks appear in a field, the spaces may be filled up by transplanting. Analogous to the Swedish turnip, in hardness and nutritive qualities, is the large yellow or Aberdeen turnip. This root is perhaps superior to the Swedish turnip, in so far as it may be raised with less difficulty. It serves the same purpose of a succedaneum to the common turnip in spring.

"5410. Consumption of the turnips." By the end of October or beginning of November, when the pastures have decayed, the turnips begin to be used for food.

5411. When sheep are to be fed, the turnips are either pulled up by the hand, and carried away, as wanted, into the fields, in which the sheep are kept, and there spread regularly upon the ground; or more frequently and economically, the sheep are at once driven into the fields of turnips, and suffered to consume them plentifully with little time to spare. In this case, the animals are not suffered to range over the whole field at first, but are confined to a space of an acre or more, by means of nets, or a series of movable rails or hurdles. When the sheep have eaten the roots very nearly, the remnant in the ground may be picked up by a little hoe (fig. 765.) or by the turnip chopper already described (3572.); and when the whole are consumed, the nets or rails, or hurdles, are moved to another division, and so on throughout the field, leaving the spaces before cleared open to the sheep to move upon. This manner of consuming the turnips affords an admirable manure to the land, and prepares it well for the subsequent crops of grain and herbage. In feeding in this manner, it is frequent to place in the field a little rack with a cover, containing a small quantity of hay, which seems to be relished by the animals amid their winter food.

5412. In the feeding of oxen, the turnips may be laid down on a dry field, as in the case first mentioned; but the proper and regular manner of feeding these animals is to supply them with the turnip in the leaf, by either of two means: first, to keep them regularly plentifully with a small quantity of what they choose to consume of it as provender, with their turnip food. Cattle are fed either by being tied up to posts in the house, or are suffered to go at large in the straw-yard. This last is greatly the better mode of feeding, the turnips are supplied from turnip stocks, and a cattle to repose in. It is well, however, that too many animals, of different strength and size, be not put together, lest they disturb each other in feeding. Sometimes courts are made and divided into separate compartments, holding only two cattle in each, and this is found to be an excellent mode. This method of feeding is the more quick, as the cattle are of a lighter kind, and are watered; cut off the leaves and tails of the turnip, giving the leaves to the younger and less valuable stock, and the bulk only to that which is to be fed.

513. Young cattle, not intended to be immediately fattened, receive only a limited portion of turnips, their principal provender being straw. By receiving a portion of turnips with their drier provender, these animals are kept in a much more healthy condition than if confined to the latter food, and continue to grow throughout the whole season, instead of pineing away at the time when green herbage can no longer be found. For the ground on which they remain too short, when keeping them in a confined condition, turnips are supplied in a limited quantity to milch cows, and in particular at the time of calving. The turnip, however, though it adds to the quantity of milk, gives it a strong and disagreeable flavour.

514. When beef cattle are fattened upon a farm, it is customary to pull up every alternate four or five rows of turnips for the cattle, leaving the remainder on the ground for the sheep, so that the land on which the turnips had grown may receive its proportion of the manure produced. (Quar. Jour. Ag. vol. I. p. 285.)

515. The advantages of eating turnips on the place of their growth by sheep, both in manuring and consolidating the ground, are sufficiently well known to every farmer. One great defect of the inferior sort of soil turnip is the want of tenacity; and it is found that valuable crops of wheat may be obtained upon very light porous soils, after turnips have been consumed. It is not uncommon to let turnips at a agreed price, for each sheep or beast, weekly. This varies according to age and size, and the state of the demand, from four-pence or less, to eight-pence or more, for each sheep weekly, and from two shillings to five for each beast. An acre of good turnips, say forty or fifty stones, which is the usual weight of an acre, is worth six guineas; and felling them for a week, keeping them in a confined condition, turnips are supplied in a limited quantity to milch cows, and in particular at the time of calving. The turnip, however, though it adds to the quantity of milk, gives it a strong and disagreeable flavour.

516. The Swedish and yellow turnips are eaten greedily by horses; and afford a very nutritive and salutary food along with hay or straw for working stock. The best mode is to steer them after previously passing them through the slicing machine, as no root requires so much cooking as the Swedish turnip. Horses will also eat the white turnip, but not freely, unless they have been early accustomed to them, as in some parts of Norfolk.

517. Cattle fattens much faster with clean turnips than with such as are dirty, and therefore Waistell recommends that they should never be given without being previously washed. "The earth upon unwashed turnips," he says, "scours the cattle, and keeps their bodies too loose and open; their dung being thin and astringent, carries off with it a white mucous matter from the bowels, which is frequently seen among the dung, the loss of which must necessarily retard the fattening of the cattle; but with washed turnips their dung is wax-like, and figured similarly to the dung of cattle fed on rich meadow hay. Cattle are also found very useful in frosty weather; for when frozen snow is thrown into the fields, which, when retained, must undoubtedly render them much less nourishing and improving to the cattle that eat them." (Waistell's Designs, Sc. p. 40.)

518. Near large towns the most profitable mode of disposing of turnips is to the cow-keepers and green-grocers.

519. The application of turnips in domestic economy is well known. They may also be used in the distillery; and a wine is said to be made from them by the London manufacturers of imitations of foreign wine.

"520. The storing of turnips is attended with too much labour and risk to be of much advantage in the greater part of the kingdom. Common turnips are never stored in any great quantity, though sometimes a portion is drawn and formed into heaps, like
potato camps, and lightly covered with straw, or preserved for some time under a shed. On these occasions, before storing up, the shaws or leaves and the tap-roots must be cut off and removed, to prevent heating and rotting. The heaps must not be covered with earth-like potatoes, for in this case their complete destruction is inevitable. This root contains too much water to be preserved for any length of time in a fresh and palatable state, after being removed from the ground; and though the loss in seassons unusually severe, particularly in the white globe variety, is commonly very great, it is probable that a regular system of storing the whole, or at the greatest part, of the crop every season would, upon an average of years, be attended with still greater loss; besides the labour and expense, where turnips are cultivated extensively, would be intolerable. (Supp. f.)  

5421. Taking up and replacing is a mode by which turnips have been preserved, by Blakie of Holkham, and some others. The mode is to cart the turnips from the field where they grow, to a piece of ground near, and to replace the tops before the winter rains set in, when, the tap-root being cut off, the plants are set on the surface of the ground, in an upright position, as close to each other as they can stand, where they keep much better than in a store during the whole season. The advantages of having them close to the homestead, in place of bringing them most probably from a distant part of the farm in wet or stormy weather, are so obvious, as fully to justify a recommendation of this practice.  

5422 Replacing and earthing have also been tried with success, especially with the Swedish turnip. Being pulled and freed from their roots and leaves, they are erected to a piece of well worked dry soil near the farmyard, and then deposited in rows, so close as nearly to touch each other in the bottom of shallow furrows, the plough covering one row as another furrow is opened. In this way many tons are quickly earthed in, and on a very small space, and they can be turned out when wanted with equal facility. (Farmer's Magazine, vol. xxxii. p. 293.) But such an extraordinary produce must have been obtained by the application of more manure than can be provided, without injustice to other crops, from the home resources of a farm; and where turnips form a regular crop in the rotation, no such produce is to be expected under any mode of culture.  

5424. The produce of turnip in nutritive matter, as proved by Sir H. Davy, was forty-two parts in a thousand; of which seven were mucilage, thirty-four sugar, and one gluten. Swedish turnips afforded sixty-four parts in a thousand of nutritive matter, of which nine were starch, fifty-one sugar, two gluten, and two extract. According to Von Thuer, 100 lbs. of turnips are equal to twenty-two of hay; and oxes to get fat on turnips ought to have one third of its weight daily.  

5425. To raise turnip seed, the usual mode is to select the most approved specimens of the variety to be raised at the season when they are full grown; and to remove all others from the field and leave them to shoot into flower stems next year, or to transplant them to a place by themselves, where they will be secure from the barrenage of other plants of their genus. In either case they must be protected by earthing up from the winter's frost and rains, and in the ripening season from the birds.  

5426. The true sort of Swedish turnip can very easily be kept by only attending to the plants when in flower, for the white yellow flower they form is the original ripens. The true sort has a brownish yellow flower. This saves the expense of transplanting if a corner or one ridge of a field can be found convenient for saving.  

5427. The Norfolk seed-growers have a sort of theory on the subject of transplanting turnips for seed which corresponds to this. According to this system, such turnips as have been sown three or four years in succession, the roots are liable to be numerous and the necks or parts between the bulbs and leaves coarse and thick; and when taken from such as have been transplanted every year, these parts are liable to become thin, and the tap-roots diminished in too great a proportion. Of course the most certain plan is to procure seed from turnips that are transplanted one year and sown the next; or, if they be transplanted once in three years, it is supposed, that the stock will be preserved in a proper state of perfection. It is stated, that the method of performing this business in the way the best known, to select such turnips as are free from all forms from the field crops, and after cutting their tops off, to transplant them, about the month of November, or following month, into a piece of ground which has been put into a fine state of tillage by roots left the previous season. It should be situated as near the house as can be, in order that the birds may be better kept from it. The seed will mostly be ready for gathering in the end of July, or in the following month.  

5428. Cultivators, however, advise that the seed collected from a few turnips thus transplanted should be preserved and sown in drills, in order to raise plants for seed for the general crop, drawing out all such as are weak and improper, leaving only those that are strong and which take the lead; and that when these have formed bulbs, such as do not appear good and perfect should be taken out, as by this means they may be procured from a locality of only a piece of land with less moisture, and of producing stronger and more hardy plants. The practice of transplanting the whole of the turnips for seed for the main crops, they contend, is not only highly expensive, but injurious, by diminishing the strength of the plants from the destruction of the tap-roots. Very good seed may, however, be raised in either of the methods that have been here described.  

5429. The best Norfolk turnip seed-growers are of opinion that unless the seed be always saved from transplanted roots, the stock will infallibly degenerate in the manner here described. The statement that transplanted roots, so far as the writer knows, has been a mere pretence with some of the growers to enable them to save two thirds of the heavy expense which attends transplanting turnips, and to get the same price for their seed as if it had been properly saved. The only exception to this is in what the Norfolk Farmers calls the 'patch turnip,' which is so tender to bear the winter. For a stock, a few sorts are taken up and protected from cold like mangold wurzel; and for a general crop the
seed is soon broadcast and not hoed, but suffered to grow like rape. So treated, the plants form very small woody sorts, which are capable of enduring frosts. (J. L.)

5430. After the seed has become fully ripened, it is mostly reaped by cutting off part of the stems, and afterwards tying up into sheaves, which, when sufficiently dry, are put into long stacks, and kept through the winter in order to be threshed or ground when it is wanted. About ten acres of turnips will yield much seed if it be left, by its readiness to escape from the pods in which it is contained, it is advisable, as a much better practice, to remove it immediately thrashed, either upon a cloth in the field where it grows, or in the barn or granary. It is then frequently put into bags, which are said to keep the seeds in a dry situation which is perfectly dry. From seed crops of this sort being subject to much injury, and loss, in different ways, the quantity of produce must be very different under different circumstances; but it may generally be said that twenty to twenty-five bushels will be got from two acres. The price of turnip seed being seldom less than seven or eight shillings the bushel, on account of the great expense in raising it, it may at first appear to be a very advantageous sort of culture; but from the exhausting nature of the crop, the loss sustained in grain, and the quantity of manure afterwards necessary, it is probable that turnips cannot only be grown to advantage, but that particular circumstances of soil and situation. In most cases it is, however, well for the farmer to raise his own seed, as that of the shops is seldom to be fully depended upon.

5431. The diseases and injuries to which turnips are liable are various. At their first appearance their leaves are liable to the attacks of the fly (Aphis aestivalis), the caterpillar, the slug, and the mildew. Their bulbs and roots are attacked by worms of different kinds; by a singular tendency to monstrosity, known provincially by the name of fingers and toes; by the anbury, by canker, and by wasting or gangrene from water or frost. Of all or most of these injurious diseases it may be observed, that they neither admit of prevention or cure by art. Under favourable circumstances of soil, climate, culture, and weather, they seldom occur; therefore all that the cultivator can do is to prepare and manure his land properly, and in the sowning season supply water when the weather is deficient in showers or the soil in humidity.

4532. The fly attacks the turnip when in the seed-leaf, and either totally devours it, or partially eats the leaves and centre-bud, so as to impede the progress of the plants to the second or rough leaves. Whether the eggs of these flies are deposited on the plants or in the soil, does not appear to be ascertained; in fact, the flies are so numerous as to be considered quite as the produce of the soil as they are of the plants. There is little doubt that the eggs of these caterpillars are deposited on the leaves of the plants by a species of moth, as the caterpillar may be detected when not larger in diameter than a hair. As preventative to this, when sowing on the turnips for a depasture for their eggs, it has been proposed to place vessels with tar in different parts of the field, the smell of which is known to be very offensive to moths and all insects; or to cause a thick offensive smoke from straw or weeds to pass over the ground at the time when it is supposed the moths or parent flies were about to commence their operations. To destroy the caterpillar itself, watering with tobacco water, lime water, strong brine, and laying on ashes, barley awns, &c. have been proposed.

5434. The slug and snail attack the plants both above and under ground, and eat both the leaves and roots. Rolling, soot, quicklime, ashes, &c. have been proposed to annoy them; but the only effectual mode is, immediately after the turnips are sown, to strew the ground with cabbage leaves, or leaves of any of the Brasicceae tribe. On these, especially if sweet from incipient decay, the slugs will pasture, and may be gathered off by women or children every morning. If many cabbage leaves, or handfuls of decaying pea haumin, or any similar vegetable be procured, as will go over a ridge or two, say at the rate of a leaf to every square yard, a whole field may soon be cleared by picking off the slugs and removing the leaves once in twenty-four hours. This method we have found most effectual, and it is extensively practised by market gardeners and other gardeners. Enzymically dis...

5435. The mildew and blight attack the turnip in different stages of its progress, and always retard its growth. Its effects may be palliated by watering and strewing the leaves with sulphur, but this will hardly be considered applicable to all cases.

5436. The worms attack the roots; and, when they commence their ravages at an early period, impede their growth, and ruin or greatly injure the crop. They admit of no remedy or prevention.

5437. The forked excrecences, known as fingers and toes in some places, and as the anbury in others, are common, and may neither be guarded against nor cured. The following account of it is given by William Spence, president of the Holderness Agricultural Society in 1811:—

5438. In some plants, the bulb itself is split into several finger-like diverging tabs. More frequently the bulb is externally tolerably perfect, and the tap root is the part principally diseased; being either wholly metamorphosed into a sort of mis-shaped secondary bulb, often larger than the real bulb, and closely attached to it, or having excrecences of various shapes, frequently not unlike human toes (whence the name of the disease, either springing immediately from its sides, or from the fibrous roots that issue from it. In this latter case, however, it is not so distasteful to resemble the human kind, but accompanied by tubers of a potato; and not seldom one turnip will exhibit a combination of all these different forms of the disease. These distortions manifest themselves at a very early stage of the turnip’s growth, and are particularly in the rough leaf, will exhibit excrecences, which differ in nothing else than size from those of the full-grown root.

5439. The leaves discover no unusual appearance, except that in hot weather they become fleeced and droop, from which the presence of the disease may be suspected without examining the roots. These continue to grow for some months, but without attaining any considerable size, the excrecences enlarging at the same time. If divided at this period with a knife, both the bulb and the excrecences are found to be perfectly solid, and internally to differ little in appearance from a healthy root, except that they exhibit a decided consistence, and are seldom found with roots of the common sort; their vessels are less large and larger ep vesicles. The taste, too, is more acid; and, on this account, sheep neglect the diseased plants. Towards the approach of autumn, the roots, in proportion as they are more or less diseased, become gasterous and rot, and are either broken (as frequently happens by high winds, and severe frost), or shrunken, by which the bulk of the root, at this period, no other vestige remains than the vacant patches which they occupied at their first appearance. There is no longer any doubt about the cause of this disease; it is the effect of the deposition of the eggs of the caterpillar near the young parts of the root, or the young parts of the bulb, which soon changing to a maggot, and ultimately to a perfect insect, eat their way out.

5440. For the prevention of this disease, marl has been recommended by Sir Joseph Banks and others; and where marl cannot be procured, it has been thought that the addition of manure of any kind, that has not borne turnips, will be advantageous; such as a dressing taken from beds, woodlands, stenches, &c. and mixed up with a good dose of lime. But lime alone has been tried in vain; and no great dependence
can be placed upon fresh mould, as this disease has been known to prevail upon lands that had scarcely ever been ploughed or turned in the crop of turnips (Farmer's Magazine, vol. xiii.). The only cultural preventive would be to hinder the insect (by laying its eggs.

5441. The canker attacks the roots, and partly the bulbs, of turnips, and is known by the ulcerated appearance it produces. Some consider it owing to the presence of too much iron in the soil, and recommend liming as a preventive.

5442. Wasting and putrefaction, from excess of water or frost, are to be prevented by earthing up the bulbs, or taking up and storing.

5443. The carrot is a biennial plant, a native of Britain; but though long known as a garden plant, it is comparatively but of recent introduction in agriculture. It appears to have been cultivated from an early period in Germany and Flanders, and introduced from the latter country to Kent and Suffolk early in the 16th century. As the carrot requires a deep soil, inclining to sand, it can never enter so generally into cultivation as the potato or turnip; but, as observed by a judicious writer, it has been too much neglected on lands where it would have yielded a more valuable product, perhaps, than any bulbous or tap-rooted plant whatever. Several contradictory experiments in its culture have been detailed in a number of publications, from which the practical husbandman will be at a loss to draw any definite conclusion; but, in a recent communication to the Board of Agriculture, from Robert Burrows, an intelligent Norfolk farmer, who has cultivated carrots on a large scale, and with great success, for several years, so accurate an account is presented of the culture, application, and extraordinary value of this root, that carrots will probably soon enter more largely into the rotation of crops on suitable soils. (Supp. &c.) This person had more experience than any one; but he, after a few years, discontinued to cultivate carrots so extensively as he did at the time the communication to the Board of Agriculture was made. The consumption of carrot seed in Norfolk had, in 1821, diminished from three or four tons a year to as many cwt.

5444. The varieties of carrot cultivated in gardens are numerous, and readily increased by the usual means; but the only sort adapted for the field is the long red or field carrot. New seed is most essential, as it will not vegetate in the second year. Old seed, or a mixture of old and new, and also the mixture of the horn carrot, the seed of which is sent over in large quantities from Holland, ought to be carefully avoided.

5445. The best soil for the carrot is a deep rich sandy loam; such a soil ought at least to be a foot deep, and all equally good from top to bottom. On any other field culture of the carrot will not answer.

5446. In preparing the soil for the carrot, it is essential to plough it before winter, that it may be pulverised by frost; and to work it well by the plough and cultivator in spring, to at least the depth of a foot. This deep tillage may be perfectly accomplished either by means of the trench-plough following the common one, or by the common one alone, with a good strength of team; but the former method is to be preferred, wherever the lands are inclined to be stiff or heavy. Three ploughings are mostly found sufficient, where the land has been previously in a state of tillage; but more may in other cases be necessary. The first ploughing should be made to the depth of ten, twelve, or fourteen inches, and be performed when the soil is tolerably dry, about the beginning of October. It may remain in this condition till towards the middle of February, when it should be turned over a second time, but in a cross direction, to nearly the same depths. In March a third ploughing may be given, in order to the putting in the seedlings. This should be lighter than the preceding ones. As soon as the last ploughing has been given in March, the land should be harrowed, and the surface made as fine as possible.

5447. In Suffolk the farmers sow carrots after turnips, barley, and peas set upon a rye-grass ley; the crops upon the first have generally been most productive; next to that they prefer the latter. In the first place, they seed off the turnips by the beginning of February, and then lay the land up in small balks or furrows, in which state it remains till the second week in March, when it is harrowed down, double furrowed to the depth of about twelve inches, and the seed sown.

5448. The climate most suitable to the carrot is the same as for the turnip; but, from the depth to which their roots penetrate, they will thrive better than the turnip in a dry and warm climate.

5449. Manure, according to some, should not be given to carrots the year they are sown, as it is alleged that when the roots meet with it they become forked, scabbed, and wonky. This, however, is chiefly applicable to cases in which recent unfermented manure has been given, or where other manure has not been properly broken in pieces and spread over the soil or in the drills. The Suffolk and Norfolk farmers, who are the best carrot-growers, always use dung; a suitable proportion of well rotted farmyard dung being constantly turned into the soil at the last ploughing in March. For it has been fully shown, by various trials detailed in The Annals of Agriculture and other books on husbandry, that though good crops of carrots may be occasionally grown without the use of manure, it is only by the liberal application of that substance that the greatest produce possible can be obtained; as they are in general found to bear a relative proportion to the quantity that may have been employed.

5450. Burrows prepares the land with a good dressing of about sixteen cart-loads per acre of rotten farmyard manure or cow-tongue ashes: the load is about as much as three able horses can draw, and, if bought, costs about four shillings and sixpence per load, besides the carting on the land. He usually sows
wheat stubbles after clover, ploughing the first time in autumn, and once more in the early part of the month of February, if the weather permits; setting on the manure at the time of sowing, which is about the last week in March, or sometimes as late as the second week in April.

5451. In Suffolk, when carrots are intended to be sown after wheat, they usually plough the stubble as soon as possible after harvest is over, in order that the land may clear itself of weeds; in December it is laid up in small balks, to receive the benefit of the frosts; in February it is harrowed down, and manured at the rate of fifteen loads per acre; the manure is ploughed in to the depth of about four inches; and in the manured land the seed sown. By pursuing this method, they say, the manure lies in the centre of the soil, and not only affords nourishment and support to the carrot in its perpendicular progress, but renders it easy to be turned up by a single ploughing, and greatly promotes the growth of the roots. In Norfolk it is the custom to sow the carrots after trench-ploughing. The manure, after being put on the land in the beginning of March, is first ploughed in with a common plough, and afterwards trench-ploughed about fourteen or fifteen inches deep; it is then harrowed very fine, and the seed sown about the middle of March.

5452. The season preferred by Burrows for sowing the carrot is the last week in March or first in April; but he prefers the first period, having generally found early-sown crops the most productive.

5453. The usual preparation of the seed for sowing, is mixing it with earth or sand, to cause it to separate more freely; but Burrows adds water, turns over the mixture of seeds and moist earth several times, and thus brings it to the point of vegetating before he sows it. "Having weighed the quantity of seed to be sown, and collected sand or fine mould, in the proportion of about two bushels to an acre, I mix the seed with the sand or mould, eight or ten pounds to every two bushels, and this is done about a fortnight or three weeks before the time I intend sowing; taking care to have the heaps turned over every day, sprinkling the outside of them with water each time of turning over, that every part of the sand or mould may be equally moist, and that vegetation may take place alike throughout. I have great advantage in preparing the seed so long beforehand; it is by this means in a state of forward vegetation, therefore lies but a short time in the ground, and, by quickly appearing above ground, is more able to contend with those numerous tribes of weeds in the soil, whose seeds are of quicker vegetation." (Supp. ii.)

5454. Crude, the French translator of Von Thaer's work, describes in a note (tom. iv. 257.) a practice nearly similar to that of Burrows. Crude uses scire (night soil) instead of earth, and waters with the drainings of dunghills. He keeps the mixture in a warm but shady situation for eight days; by that time the seed is nearly ready to vegetate, and he sows it immediately.

5455. The quantity of seed when carrots are sown in rows is two pounds per acre, and for broadcast sowing five pounds. Burrows sows ten pounds per acre in the broadcast manner.

5456. The usual mode of sowing the carrot is broad-cast; but a much better mode in our opinion would be to sow them in rows at twelve or fourteen inches' distance; drawing the drills, and hoeing the intervals with any suitable drill and hoe.

5457. The most common practice, when carrots are best cultivated, is the hand or broad-cast method, the seed being dispersed as evenly as possible over the land, after the surface has been reduced to a very fine state of pulverisation by harrowing, in order to provide a suitable bed for it to vegetate in; being then covered in by means of a light harrow. As the seed of the carrot is not of a nature to be deposited with much regularity by the drill, and as the young plants can be easily set out to proper distance in the rows, the most appropriate method of sowing such sort of seed into the ground; and an additional proof of it is indeed found in its being that which is almost universally adopted in those districts where carrot husbandry is practised to the greatest extent. But with the view of having the seed scattered uniformly, and at the same time to save the great expense of hand-labour in hoeing the crop, the drill method has been attempted by some cultivators, but we believe without complete success. The work is finished in equidistant rows at the distance of from twelve to fifteen or eighteen inches from each other, according to the mode of hoeing that is practised. In this kind of drill, the latter part of drill-machines, which strike the land into small furrows by hoes or other implements contrived for the purpose, and then cast the seed over the ground by the hand, covering it either by slight harrowing, or hoeing in the tops of the ridgelets. It is added, that "in this method, where a drill-machine is used, it has been advised by an intelligent cultivator to deposit the seed to the depth of one inch in the rows, leaving the spaces of fourteen inches between them as intervals; but the seed in these cases being previously steeped in rain-water for twenty-four hours, and then to be sown, after which it is mixed with saw-dust and damp sand, in the proportion of one peck and a half of each of these to a pound of the seed. The land is afterwards lightly harrowed over once. Two pounds of seed in this mode are found, as it has been observed, sufficient for an acre of land."
PRACTICE the throw but have practice of for acre, beginning carrots but completely at good in injured rows: time the carrots in them mankind horses soiling the carrots in drawing over the heaps which should be done in the latter end of April, when the carrots begin to sprout at spring, and must be healthy and not utterly off and laid by themselves; by this means, carrots may be kept the month of June out in a high state of perfection.” (Communications to the Board of Agriculture, vol. vi. p. 72)

5463. Storing a whole crop of carrots may be a desirable practice when winter wheat is to follow them, in which case the same mode may be adopted as for turnips or potatoes, but with fewer precautions against the frost, as the carrot, if perfectly dry, is very little injured by that description of weather.

5464. The produce of an acre of carrots in Suffolk, according to Arthur Young, is at an average 350 bushels; but Burrows’s crops averaged upwards of 800 bushels per acre, which considerably exceeds the largest crop of potatoes.

5465. The uses to which the carrot is applied in Suffolk are various. Large quantities are sent to the London markets, and also given as food to different kinds of live stock. Horses are remarkably fond of carrots; and it is even said, that when oats and carrots are given together, the horses leave the oats and eat the carrots. The ordinary allowance is about forty or fifty pounds a day to each horse. Carrots when mixed with chaff, that is, cut straw, and a little hay, without corn, keep horses in excellent condition for performing all kinds of ordinary labour. The farmers begin to feed their horses with carrots in December, and continue to give them chiefly that kind of provender till the beginning or middle of May; to which period, with proper care, carrots may be preserved. As many of the farmers in that country are of opinion that carrots are not so good for horses in winter as in spring, they give only half the above allowance of carrots at first, and add a little corn for a few weeks after they begin to use carrots.

5466. The application of the carrot to the feeding of working cattle and horses is thus detailed by Burrows: — “I begin to take up the carrot crop in the last week of October, as at that time I generally finish soiling my horses with lucern, and now solely depend upon my carrots, with a proper allowance of hay, as winter food for my horses, until about the first week of June following, when the lucern is again ready for soiling. By reducing this practice to a system, I have been enabled to feed ten cart-horses throughout the winter months for these last six years, without giving them any corn whatever, and have at the same time effected a considerable saving of hay, from what I found necessary to give to the same number of horses belonging to the usual form of country, I fed my horses with corn and hay. I give them to my cart-horses in the proportion of seventy pounds’ weight of carrots a horse per day, upon an average; not allowing them quite so many in the very short days, and sometimes more than that quantity in the winter. I have never witheld them for a single day. The men who tend the horses slice some of the carrots in the cut chaff or hay, and barn door refuse; the rest of the carrots they give whole to the horses at night, with a small quantity of hay in their rack; and with this food my horses generally enjoy uninterrupted health. I mention this, as I believe that some persons think that cattle cannot feed on carrots as they do on grass, and that injurious to their constitution, and mankind no better formation, and are taken up at random, or inherited from their grandfathers. So successful have I been with carrots, as a winter food for horses, that with the assistance of lucern for soiling in summer, I have been enabled to prove by experiments conducted under my own personal inspection, that an able Norfolk team horse, fully worked two journeys a day, winter and summer, may be kept the entire year round upon the produce of only one statute acre of land. I have likewise applied carrots with great profit to the feeding of hogs in winter, and by that means have made my straw into a most excellent manure, without the aid of neat cattle; the hogs so fed are sold on Norwich hill to the London dealers as porkers.” The profit of carrots so applied he shows in a subsequent statement, together with an experiment of feeding four Galloway bullocks with carrots, against four others fed in the usual way with turnips and hay. (Communications to the Board of Agriculture.)

5467. In comparing the carrot with the potato, an additional circumstance greatly in favour of the former is, that it does not require to be steamed or boiled, and it is not more difficult to wash than the potato. These and other circumstances considered, it appears to be the most valuable of all roots for working horses.

5468. The use of the carrot in domestic economy is well known. Their produce of nutritive matter, as ascertained by Sir H. Davy, amounts to ninety-eight parts in one thousand, of which three are starch, and seventy-five sugar. They are used in the dairy in winter and spring to give colour and flavour to butter. In the distillery, owing to the great proportion of sugar in their composition, they yield more spirit than the potato: the usual quantity is twelve gallons per ton. They are excellent in soups, stews, and haricots, and boiled whole with salt beef.

5469. To save carrot seed, select annually some of the most perfect and best-shaped roots in the taking-up season, and either preserve them in sand in a cellar till spring, or plant them immediately in an open airy part of the garden, protecting them with litter during severe frosts, or earthing them over, and uncovering them in March following. The seed is in no danger of being contaminated by any other plant, as the wild carrot, even should it happen to grow in the neighbourhood, flowers later. In August it will be fit to gather, and is best preserved on the stalks till wanted. This is the most
certain mode of procuring genuine and new seed, but still it will be found advisable to change it occasionally.

5470. The diseases of carrots are only those which are common to most plants, such as mildew, insects, &c. The mildew and worms at the root frequently injure crops, and are to be guarded against as far as practicable by a proper choice of soil, season of sowing, and after-culture.

Sect. IV. The Parsnep.—Pastinaca sativa L.; Pentáudria Digitá L., and Umbelifere J. L. Pauál, Fr.; Pastinake, Ger.; Pastinaca, Ital.; and Zanahoria, Span.

*5471. The parsnep is a biennial plant with a fusiform root like the carrot, and nearly equal in its products of nutritive and saccharine matter. It is a native of most parts of Europe and generally cultivated in gardens, but is only of late and very partial introduction as a field plant. Its culture has been chiefly confined to the Island of Jersey, where it attains a large size, and is much esteemed for fattening cattle and pigs. It is considered rather more hardy than the carrot, and its produce is said to be greater. It may be sown either in autumn or spring, and its seed admits of drilling by machinery. The plants when they come up are more easily recognised than carrots, and consequently their culture is on the whole more simple, less dependent on manual labour, and, therefore, more suited to farming. For the rest, their culture is the same as that of the carrot.

5472. The variety best suited for the field is the large Jersey, the seed of which should be procured from the island, as that of the garden parsnep sold by the seedsmen never attains the same size.

5473. The soil, preparation, and manure for this plant are the same as for the carrot.

5474. The quantity of seed for sowing in drills is from four to five pounds per acre, and for broad-cast six or eight pounds. It must always be new, as two years' seed does not come up freely. It may or may not be prepared by steeping; but it requires no earth or sand, or rubbing, like carrot seed, as it passes freely through the same drill that will sow tares or peas.

5475. The time of sowing is generally about the middle of February; but some sow in September, in which case the seed does not vegetate till early in spring. The latter method, however, is obviously against the culture of the soil, which must thus remain a year in a consolidated state.

5476. The manner of sowing is generally in drills at fifteen or eighteen inches' distance; but some sow broad-cast, and harrow in the seed; and in Jersey parsneps and beans are generally cultivated together. The beans are first dibbled in, and afterwards the parsnep seed scattered over the surface and harrowed. It is acknowledged that a good crop of both plants is never obtained; and therefore, though this mode may be found to answer in the mild climate of Jersey, it is not to be imitated in other places. Drills and broad-cast without any intermixture of plants are the only advisable modes.

5477. The after-culture and taking up are the same as for the carrot, with this difference, that the parsnep when sown broad-cast is generally thinned out to twelve inches, at an average, plant from plant; and, when in rows eighteen inches apart, to nine inches in the row.

*5478. The produce is said to be greater than that of carrots; and the economical application the same. In the fattening of cattle it is found equal if not superior, performing the business with as much expedition, and affording meat of exquisite flavour and a highly juicy quality. The animals eat it with much greediness. It is reckoned that thirty perches, where the crop is good, will be sufficient to fatten a perfectly lean ox of three or four years old, in the course of three months. They are given in the proportion of about thirty pounds' weight morning, noon, and night; the large ones being split in three or four pieces, and a little hay supplied in the intervals of those periods. Indeed, the result of experiment has shown that not only neat cattle, but hogs and poultry, become fat much sooner, and are more bulky, than when fed with any other root or vegetable; and that the meat is more sweet and delicate. The parsnep is excellent food for cows; and, with hay during winter, the cows of Jersey and Guernsey yield butter of a fine yellow hue, of a salmon tinge, as excellent as if they had been in the most luxuriant pasture. In these islands beans are cultivated along with parsneps, in double rows, twelve feet asunder, and the beans eighteen inches apart every way. The beans are planted first, and the ground afterwards harrowed, and the parsneps sown broad-cast. (Com. to B. of Agr. vol. i. p. 215.)

5479. Parsnep leaves, being more bulky than those of carrots, may be mown off before taking up the roots, and given to cows, oxen, or horses, by which they will be greedily eaten.

5480. The use of the parsnep in domestic economy is nearly the same as that of the carrot. They are much esteemed to salt fish, and are sometimes roasted for that purpose.

2 K
Their produce in nutritive matter is 99 parts in 1000, of which 9 are mucilage and 90 sugar. Gerarde says, that a very good bread was made from them in his time. They afford as much spirit as the carrot, and make an excellent wine.

5481. To save parsnep seed, proceed as with the carrot. The parsnep, being more hardy and luxuriant than the carrot, is less liable to the mildew and worms, but equally so to become forked if the soil be not deep and well pulverised, and the manure minutely divided and equally distributed.

Sect. V. The Field Beet. — Beta L.; Pontandria Digynia L., and Chenophobus J. Bertanre Champêtre, Fr.; Mangold-würzel, Ger.; Biottola, Ital.; and Betarraga, Span.

5482. The field-beet, commonly called the mangold-würzel, and sometimes erroneously the root of scarcity (in German mangel würzel), is supposed by Professor Thaer to be a mongrel between the red and white beet. It has a much larger bulb than either, and that bulb, in some varieties, grows in great part above ground. It has been a good deal cultivated in Germany and Switzerland, both for its leaves and roots; the leaves are either used as spinach or given to cattle; and the roots are either given to cattle, used in distillation, or in the manufacture of sugar. The culture of the field-beet in Britain is very recent, and it may be questioned whether it has any advantages over the turnip for general agricultural purposes. It admits, however, of being cultivated on ridgelets and with as little manual labour as the turnip, while it will prosper on a stronger soil, and near large towns it is not liable to the depredations usually committed on turnips or carrots, as the root is unpalatable either raw or boiled.

5483. The variety preferred in Germany is one slightly tinged with red for cattle, and the pale yellow variety for the distillery and sugar manufacture. The seed must not exceed a year old, and great care should be taken that the seed of the common red and white beet are not mixed with it. The seed of every variety of beet is very apt to degenerate.

5484. Any soil will suit this plant provided it is rich: immense crops have been raised on strong clays; but such soils are not easily prepared for this sort of crop, and are also ill adapted for after-culture.

5485. The preparation should be exactly the same as for turnips; and the seed should be sown on the ridgelets in the same manner. Some, however, dibble in the seed in order to save the expense of thinning. The seed for sowing is the same as that of the parsnep. The soil should be thoroughly trenched in March. The after culture consists in horse-hoeing, hand-hoeing, and weeding, as in the culture of the turnip, and the plants are thinned out to about the same distance in the rows. Blanks may be filled up by transplanting, or, as in the case of the Swedish turnip, whole crops may be reared in this way; but the produce is never so large. As the transplanting, however, takes place in May, more time is afforded, and drier weather obtained for cleaning the soil. The plants are set by the dibbler along the centre of the ridgelets, which are previously consolidated by rolling.

5486. The produce is, ceteris paribus, about the same as that of the Swedish turnip, but the nutritive matter afforded by the beet is 136 parts in 1000, of which 13 are mucilage, 119 sugar, and 4 gluten. According to Von Thaer, they afford ten per cent. of nutritive matter, and are in that respect to hay as 10 to 46, and to potatoes as 20 to 46. An acre would thus appear to afford more nourishment than turnips, carrots, or parsnips.

5487. Practical men are not agreed as to the value of this root, compared with the Swedish turnip; but the majority seem to think, that as a food for milk cows, the mangold is to be preferred, more especially as it gives no unpleasant taste to the milk and butter. It has this advantage over turnips, that it thrives better than they do in a dry warm season, being a plant that naturally requires more light and heat than the turnip.

5488. The application of the field-beet is almost confined to the fattening of stock, and feeding of milk cows. Near London they are in repute for the latter purpose; and, according to Von Thaer, they cause a great increase of milk, as well as improve its flavour. The tops are first taken off, and given by themselves; and then the roots are taken up, washed, and given raw. The roots are much more easily injured by frost than the turnip, carrot, or parsnip, and are stored with difficulty. The leaves make a very good spinach, but the roots cannot be used in cooking like those of the red beet. In the distillery it is nearly half as productive as the potato; but, according to Von Thaer, it is not likely to yield much profit in the manufacture of sugar.

5489. The manufacture of sugar from mangold würzel is still, however, carried on in France, and, although we think it can never ultimately compete with that from the cane, it seems of late years to be on the increase. We shall therefore give a short account of the process, premises that the greatest quantity of sugar is obtained from the greatest bulk of root, but rather from small roots produced from dry calcareous soils, at the rate of from fifteen to twenty tons an acre. One cwt. of sugar is the general produce obtained by the most perfect apparatus from one ton of root. As soon as the leaves begin to turn yellow, the root may be said to have arrived at maturity; and it is time to take up the crop, and to begin the process of sugar-making, an operation which continues from October to February in the larger manufactories. Take the roots up dry, and keep them so; the smaller the heap the better, because the least fermentation will effectually prevent the formation of sugar. The difference in amount and quality of sugar is always in favour of that made at the beginning of the season. The root, in keeping, undergoes a chemical change, often amounting to a total loss of its saccharine matter; although its outward appearance indicates no such change.

5490. Process of sugar-making. The roots should first be washed, and then rasped, to reduce them to a state of pulp. Of course, in large manufactories, they are provided with rasping machines; and it is
somewhat difficult to find a substitute on a small scale. I should imagine, though, that a stout iron plate, punched with triangular holes, the rough edges of which are left standing, somewhat after the manner of a nutmeg-grater, might answer the purpose, only that I would have it somewhat concave instead of convex. On the rough side of the plate I would rub the roots by hand. If there should be a cider-mill and press without a reasonable distance, it might answer as well. I would use the juice for the same purpose, and pass them through the mill. When they are so, or any other means they are reduced to pulp, the juice should be pressed from the pulp, which is thus done:—It is put into canvas bags, not into press-cloths, as the juice is to be left in the bags and let them drain slowly. The bags should be so fitted as, when pressed, to occupy about an inch in depth. Most manufactories use about twenty-five of these bags at one pressing, but this depends on the power of the press. Between every bag of pulp is laid a sort of outer barrier, to allow the juice to percolate freely from the press into the juice-cistern below. The operation of pressing should immediately follow that of rasing. This point should be particularly attended to.

5491. Defecation. The juice being expressed from the pulp, the next process is the defecation of the juice. There should be a large cistern in which the juice will be immersed. Get up the fire till the thermometer indicates 170° or 175°. Then add slaked lime (quick) previously mixed with water, at the rate of five or six pounds for every 100 gallons of juice. Stir it well up, and skin the liquor if it till the sugar begins to evaporate. Add sulphuric acid in small portions, diluted with six times its bulk of water, to neutralise the effect of the lime, stirring it briskly each time. The proper quantity is ascertained by carefully examining the juice every time the acid is added, with a drop of syrup of violets in a spoon, which ought to turn of a green colour. About thirty ounces of the acid to every 100 gallons of juice will be necessary. This done, the fire is quenched, and the boiler left to settle for half an hour; at the end of which time, the liquor is drawn off; by some, bullrock’s blood is added when the temperature of the juice reaches 185° in the proportion of two pints and a half to every twenty gallons of juice. Some, too, apply the sulphuric acid to the juice when cold, instead of hot, viz. before the boiler-fire is lighted; and one recommends its being applied to the pulp before it goes into the boiler: but all this practice will decide.

5492. Concentration. The next process is concentration of the juice, which means nothing more than evaporating it from the water therein contained. This is effected by flat pans, over a brisk fire, but not so as to burn the syrup, which is the great danger in this operation. When reduced in pan I from 4 to 2 inches or so in depth, it is put into a smaller pan (2), and reduced to the same depth, and afterwards to a third of an hour or an hour, and the syrup limited is the syrup rises, and threatens to overflow the pan, put in a small lump of butter, which will make it subside.

5493. Clarification. This the next operation, and may be carried on in one of the pans used for concentration (1) (some) or in a special vessel; the syrup is now applied to the boil crying 190°, and then run into moulds; but the cooling is very gradual. The pan is covered, and the heat kept in by closing the edges with a flannel. The syrup is then poured into large earthen moulds cone-shaped, and with a hole at bottom, through which the molasses drains. This hole is temporarily stopped till the molasses begins to settle, and requires a mouth to separate galls. As it rises, it crystallises. The syrup, whilst filling, is at 67° to 77°; but, in the course of purging, it is raised to 195° and even 205°, which expedites the flow of the molasses. Our next process is turning the moulds, i.e. setting the cones on their bases, and taking them out of the mould; when the syrup has become dry the syrup: this is cut off, and boiled over again with the molasses. Thus far the process of making brown sugar: refining is a different business, and one which there is no occasion to particularise here. It is to be observed, that copper utensils are preferred to those of iron, the latter having a chemical effect on the sugar. (Gard. Mag. vol. VI. pp. 150, 191.)

5495. To save seed, select the finest specimens, preserve them in sand during winter and plant them in an airy part of the garden in March. The rest is easy.

5496. To diseases no plant is less liable than the beet.

5497. The cabbage tribe is of the greatest antiquity in gardens, and most of the species may be cultivated in the fields with success. For the common purposes of farming, however, there can be little doubt that they will afford less profit than any of the plants hitherto treated of in this chapter; but near large towns or sea-ports they may answer the purpose of the farm-gardener. Cabbage culture, Brown observes, is much more hazardous, far less profitable, and attended with infinitely more trouble, than that of turnips; while the advantages to be derived are not, in our opinion, of a description to compensate the extra hazard and trouble thereby incurred.

5498. The culture of cabbage has been strongly recommended by several speculative agriculturists, and examples adduced of extraordinary produce and profits; but any plant treated in an extraordinary manner will give extraordinary results; and thus an inferior production may be made to appear more valuable than it really is. One reason why so much has been said in their favour, by Arthur Young and other southern farmers, is, that they compare them with the produce of turnips, which, in the south of England, is averaged at only fifteen tons per acre.

5499. The variety of cabbage, cultivated in the fields for cattle, is almost exclusively the large field cabbage, called also the Scotch, Strasburg, drumhead, &c. For the purposes of domestic economy, other varieties of early and late cabbage, as the York, Barter, sugar-loaf, Imperial, &c. are grown; and also German greens, Savoy cabbage, and even Brussels sprouts and broccoli.

5500. The cow cabbage, Cécreneau cole, or tree cabbage (Brásica oléresca L. var. acéphala Des.; Chou cailler, Chou à taches, Chou branche, Chou en arbre, Chou mille fées, Fr.; Caulet, Flem.), is much cult.
tivated for milk cows in French Flanders, the Netherlands, and in Jersey and Guernsey; and it has been introduced, at different periods, into this country, without having ever come into general culti-
vation. The creamy Flanders milk cows from the French variety having red leaves; and the Cha-
vert branch, the Che mille lcs du Poitou, differs from the first in not growing quite so high, and in
form a somewhat tufted head. No variety among these, and the many that might be named, appear so
suitable for field culture in the climate of this country as that of the Scotch milk cow. 5504. The cow cabbage is sown from about the 20th of August to the 1st of September, in a
soil, and planted out from November to January and February in succession, at from twenty to
thirty inches' distance, in a good, substantial, well-manured soil. This plant is more prodigious for
requires a better soil; but perhaps the same plant produces so large a quantity of nutrient during its period
of vegetation. About the month of April they begin (from the first crop) to strip the under leaves; cut
them in small pieces; mix them with sour milk and bran, or other farinaceous substances; and give them as
food to ducks, geese, hoys, &c. During the whole summer they continue stripping the plant is a shoive
stated, until it attains the height of from six to twelve feet; and if a scarcity of herbage prevails, the green
leaves form excellent food for cows and oxen, with alternate feeds of hay and straw. The tops and side
shoots are excellent at table during winter and spring. They support scarlet runners and other sweet peas,
and as crosses forter for farm buildings, under thatch, and have been known to last more than half a century, when kept dry, for the latter purpose. (Gard. Mag.
vol. v.)

5502. Any soil that is rich will suit the cabbage, but a strong loam is preferred. The
best mode of preparation for field cabbage is that for potatoes or turnips, the plants being
dabbled along the centre of each ridgelet. For early cabbage no ridgelets are required,
as the plants are inserted in rows, by a line, at much narrower distances.

5503. The season for planting, for a full crop of field cabbages, is usually March;
but cabbages may be planted as late as June, and produce a tolerable crop by
November; and in this way they may sometimes be made to succeed an unsuc-
cessful sowing of turnips. The plants used in March should be the produce of seed
sown, in an open loamy part of the garden, in the preceding August; but those planted
in May or June may be the produce of seed sown in the February or March of the
same year.

5504. The preparation given to the plants consists in pinching off the extremity of their tap-root, and
any tubercles which appear on the roots or mix, in a particular soil, and water, to protect the fibres and pores of the root and stem from the drought. The
plants may then be inserted by the dibber, taking care not to plant them too deep, and to press the earth firmly
at the lower extremity of the root. If this last point is not attended to in planting by the dibber, the
plant will either die, or, in the growth of the头部 of the rain or rain, their progress will be very slow.
When the distance between the ridgelets is twenty-seven inches, the plants are set about two feet asunder
in the rows; and the quantity required for an acre is about 8000 plants. Some recommend sowing as for
turnips; but, by this mode, one of the advantages of a green crop is infringed, viz., the time given
to the land. Where cabbages are sown, that operation must be performed at least a month sooner
than if they were planted; consequently, the best month of the closing season is lost. To plant or sow
a green crop on land in good heart, that does not require cleaning, will seldom be found good husbandry.
It may be sown near large towns, where roots and other green produce sell high, but it can never enter into
any general system of farming.

5505. The after-culture consists in horse and hand-hoeing and weeding; and the crop is
taken by chopping off the heads with a spade, leaving an inch or two of stalk to each.
They may be preserved by housing, but only for a short time. The produce is said to
be from thirty-five to forty tons per acre. Sir II. Davy found that 1000 parts of cabbages gave seventy-three of nutritive matter, of which forty-one are mucilage, twenty-four
ascorbinic matter, and eight gluten.

5506. The application of the field cabbage is generally to the feeding of milk cows, and sometimes
to the fattening of oxen and sheep. For the former purpose, great care must be
taken to remove the outside decaying leaves; otherwise they are apt to give an un-
pleasant flavour to the milk and butter. Cabbages are also eaten by swine and horses,
and are reckoned excellent food for sheep that have newly dropped their lambs, and for
calves. A cow will eat from 100 to 150lbs. of cabbage per day, and a sheep ten
or twelve pounds, besides a moderate allowance of hay. Some farmers consider that eves
fatten faster on cabbages than on turnips, and that ewes having lambs are much more
prolific in milk when so fed. (Country Times, Feb. 8. p. 47.) Early or garden cabbages are
sold to green-grocers, or to the consumers, or to ships' victuallers for the purpose of
being pickled or made into sour crust.

5507. Salted cabbage, or sauerkraut, is thus prepared in Germany:—Any sort of cabbage to kail, or
even turnips and kidneybeans, may be prepared in this way; but white, compact-headed, large cabbages
are preferred, and next compact-headed red cabbages. The first process of preparing them is to scoop
out the inner part of the seed with an iron instrument or scoop; they are then cut into small shreds
by a wooden machine, composed of a flat board or tray, which has a ledge on two sides, to steady a box or
frame into which the cabbages are put. In the middle of the board are four flat pieces of steel, similar to
the steel part of a spokeshave, placed in an oblique direction, with slightly raised sides, and little
rabbets, which give them when cut, the sides of which are first washed with vinegar. A man stands
on a chair by the barrel, with clean wooden shoes on, whose business it is to salt and prepare them, which
is done in the following manner: the man first takes as much of the cut cabbage as covers about four
inches above the bottom; he next stews upon it two handfuls of salt, one handful of unground pepper,
and a small quantity of salad oil; he then gets into the barrel, and treats it down with his wooden shoes
till it is well mixed and compact. He next takes another layer of cabbage, and puts salt and pepper on it
as before, and treats it again, and so goes on till the barrel is filled. A barrel is then placed on it, and
upon the board some very heavy weights are put; and it remains so ten or fifteen days, when it partially
ferments, and a great deal of water swims on the surface: it is then put into the cellar for use. The men
who prepare sauerkraut are Tyrolese, and carry their machine (fig. 767.), which has not been invented more than ten or twelve years, on their backs from house to house. This machine contains a cutting tray (a), box into which the cabbages are placed (b), scoop (c), and tub into which the shreds fall (d). (Gard. Mag. vol.ii. p.34.)

5508. Newton's machine for chopping cabbage or other vegetables, roots, or meat (fig. 768.), consists of five knives let into an iron plate, and the latter is screwed to the working bar. The knives are fastened, by bolts passing through them, close under and above the iron plate. The sliding plate is for the purpose of preventing the meat from being scattered; and to this plate are added scrapers, which are screwed underneath, for the purpose of cleaning the knives at every stroke. A spring raises the knives, and enables any person to chop at least twenty times as much meat, in the same time, as can be done by the common mode. The length of the knives being equal to the breadth of the trough, no meat can possibly escape the knives; nor will the meat require so much turning as is usually wanted. When it does require turning, it is easily done by alternately pressing the knives at either end of the trough, sliding them towards the middle. The machine is also applicable for cutting fat, suet, &c., previously to rendering them into tallow; likewise to chopping madder and other roots for calico printers, or as used in their recent state for dyers; and for dividing potatoes, carrots, and other esculent roots, cabbage for sauer kraut, and roots used in feeding cattle. (Smith's Mechanic, vol.ii. p.366.)

5509. To save cabbage seed, select a few fine specimens, and plant them by themselves where they will be in no danger of being contaminated by others of the Blástica tribe when in flower. The seed will keep many years.

5510. The diseases of cabbages are the same as those of the turnip, with the exception of the forked excrescence. On the roots of the plants are frequently found knobs, which, in the preparation for transplanting, should, as we have already observed, be carefully removed.

Sect. VII. Other Plants which might be cultivated in the Fields for their Roots or Leaves, as Food for Man or Cattle, in a recent State.

5511. Every hardy garden plant may be cultivated in the fields, and with very little manual labour. Accordingly we find onions, spinach, cress, radishes, and even cucumbers, grown by farmers, or farm gardeners in the neighbourhood of the metropolis, and also in other places. None of these plants, however, can be considered as belonging to agriculture; nor should we notice those which follow, but because they have been tried and recommended by zealous cultivators, and are treated of in some works on farming. No plant can be considered as belonging to agriculture that is not in sufficient demand, or of sufficient general use in feeding stock, as to admit of its frequent occurrence in rotations; and such certainly cannot be said to be the case with the Jerusalem artichoke and lettuce, now about to be noticed.

5512. The Jerusalem artichoke (Helianthus tuberosus L.; Topinambour, Fr.) is a tuberous-rooted plant, with leafy stems from four to six feet high. It thrives well on soft moist soils, and even, it is said, on moist peat soils; and it is alleged that its tops will afford as much fodder per acre as a crop of oats, or more, and its roots half as many tubers as an ordinary crop of potatoes. (Agricultural Magazine, 1807-8.)

The soil may be cultivated in all respects like the potato. The tubers, being abundant in the market gardens, are to be had at little more than the price of potatoes. The fibres of the stems may be separated by maceration, and manufactured into cordage or cloth; and this is said to be done in some parts of the north and west of France, as about Hagenau, where this plant, on the poor sandy soils, is an object of field culture.
The common Coletuce (Lactuca sativa. L.) has been grown for feeding pigs, and other purposes. Arthur Young informs us, in his Calendar of Husbandry, that he first observed the sowing of lettuces for hogs practised, on a pretty regular system, on the farm of the late Mr. H. J. Young, an intelligent cultivator not at all a whimsical man in Sussex. He had every year an acre or two, which afforded a great quantity of very valuable food for his sows and pigs. He adds, that it yields milk amply, and all sorts of swine are very fond of it; and he thinks that the economical farmer would do well to keep his hogs should take care to have a succession of crops for these animals, that his carts may not be forever on the road for purchased grains, or his granary opened for corn oftener than is necessary. To raise this sort of crop, the land should have been ploughed before the winter frosts, turning in by the hand, or small loads of rich dung per acre, and making the ridges of the right breadth to suit the drill-machine and horses, so that in that month of March nothing more may be necessary than to scarify the land, and to drill the seed at one foot equi-distant, at the rate of four pounds of seed per acre. Where the stock of swine is large, it is proper to drill half an acre or an acre of lettuce in April, the land being first harrowed and ploughed as directed above, being also sculled in February and March, and well harrowed, repeating it before drilling; and at this period, the crop which was drilled in March (a succession being essentially necessary) should be thinned in the rows by hand, to about nine or ten inches apart; if this necessary attention be neglected, the planters, he says, draw themselves up weak and poor, and will not recover it. Women do this business as well as men. When about six inches high, they should be horse-hoed with a scarrifier or scuffle, having the hoes about four inches, or at most five inches in width. With this sort of green food, some kind of meal or other dry meat should be combined, as without it it is apt to prove very laxative, &c. This same cultivator is not likely to be followed by any rent-paying farmer who can grow any of the cloyers, turnips, or potatoes. The quotation affords a good specimen of Arthur Young's mode of writing on agricultural subjects.

The chicory, wild endive, or succory (Cichorium intybus L.; Cicoria sauvage, fr. 700.) has long, thick, perpendicular roots, a tuft of endive or lettuce-looking leaves; and, when it shoots into flower, its stems rise from one to three feet high, rigid, rough, branched, and clothed with leaves and blue flowers. It is found in dry calcareous soils in England, and in most parts of Europe of similar or greater temperature. It is cultivated in France as a herbage and pasturage plant, and in Germany and Flanders for its roots which are sold in the market. It was first cultivated in this country, about 1780, by Arthur Young, who holds it in very high estimation. It is of such consequence, he says, for different purposes of the farm, that on various sorts of soil the farmers cannot without its use, make the greatest possible profit. Where it is intended to lay a field to grass for three, four, or six years, in order to rest the land, or to increase the quantity of sheep food, there exists for it. There is no plant to rival it. Lucern, he says, demands a rich soil, and will always be kept as long as it is productive; but on inferior land it is not an equal object. Upon blowing sands, or upon any soil that is weak and poor, and wants rest, there is no plant, he supposes, that equals this. On such sort of blowing poor sandy lands as many districts abound with, especially in Norfolk and Suffolk, it will yield a greater quantity of sheep food than any other plant at present in cultivation. On fen and bog lands, and peat soils, it also thrives to much profit. On all land where clover, from having been too often repeated, is kept in a bad state, it has been of great advantage. It does very well for soil ing cattle, both lean and fattening. It is of excellent use for those who keep a large stock of swine; and it does exceedingly well in an alternate system of grass and tillage, as it will last four, five, six, and even more years; but it should not be sown with any view of making hay in this climate, though it forms a considerable proportion of many of the best meadows in the south of France, and in Lombardy. It has, however, it adds, been objected to, on the ground of its rising and becoming a species of grass in certain circumstances not guarded against it, will, he says, happen; but not more than with lucern, nor so much. But who, he asks, ventures to forbid chicory culture on account of this quality, which is really founded on its merit? When the land is ploughed, says he, only use a broad sharp share, and harrow in tares for feeding or sowing, or break it up for turnips, and then plant it, as the planters are old. All the symbols show; that a bush or two, when the plants were a year old. All the symbols show; that a bush or two, when the plants were a year old.

5515. The culture of chicory is the same as of clover. As the plant is grown in gardens for culinary purposes, the seed may be procured in the seed-shops, gathered in many places from wild plants, or saved by the grower. It is small, flat, blackish, and resembling the fresh green peas, from eight to twelve pounds on an acre are usually sown. The culture of this plant for its roots has been noticed in the outline of the agriculture of Flanders, and will be adverted to in a succeeding Chapter. 5516. The rough comfrey (Symphytum aspernum L. fig. 776.), a perennial from Siberia, has been brought into notice by Mr. Ellis, late of Longleat. In the years 1850-7, he observed, accidentally, how extremely fond cattle were of this plant, even eating it down to the roots when an opportunity occurred; and as he knew from long experience, that it would, even in dry ground, produce herbage in the middle and latter end of

*5517. The day lily (Hemerocallis fulva L., fig. 771.) was brought into notice by Mr. Ellis, late of Longleat. In the years 1850-7, he observed, accidentally, how extremely fond cattle were of this plant, even eating it down to the roots when an opportunity occurred; and as he knew from long experience, that it would, even in dry ground, produce herbage in the middle and latter end of...
April, equal in quantity to any water meadow, the extreme facility with which it may be propagated and grown in almost any soil and situation, and also its apparently nutritious nature, he was induced to give it a trial in a plot of ground of about twenty rods, attached to the cottage in which he lived. He did so, and after two years' trial found the day lily produce a supply of green food in April and towards the middle of May, when there is little or no pasture grass, and never could detect any unpleasant flavour in the milk or butter, though given in considerable quantities. The day lily, of which there are two species, differing very little in appearance, H. flava and fulva, is a perennial of great duration, rapid increase, and of easy propagation by division. It certainly well deserves trial as a permanent herbage plant, especially for the cottager and small farmer. (Gard. Mag. vol. v. p. 441.)

CHAPTER V.

Culture of Herbage Plants.

5518. The cultivation of clovers and other herbage plants, used exclusively as food for live stock, is comparatively a modern improvement. They were known, as we have seen, to the Greeks and Romans, and cultivated from a very early period in the low countries; but do not appear to have attracted much notice in Britain till the sixteenth century, when our frequent intercourse with Holland led to the introduction of some of our best field plants and agricultural practices. At present clovers enter largely into the succession of crops, on all soils, and in every productive course of management. Before they were introduced into cultivation, it was necessary, when land was exhausted by grain crops, to leave it in a state of comparative sterility for several years, before it became either valuable as pasture or again fit for carrying corn; but at present clovers are not only indispensable in the cultivation of white and green crops alternately, upon very rich soils, but are the foundation of convertible husbandry on land that is not so rich as to permit of a constant aration, and which therefore requires two or more years' pasturage at certain intervals. Lucern and saintfoin, though of much less value as general crops, are valuable plants in particular situations; more especially the latter, which will produce good crops on dry chalky and limestone soils, where most other agricultural plants, and even grasses, would barely maintain their existence.

5519. The characteristic points of culture of this class of plants are broad-cast sowing, moving, sowing, and hay-making; and that when cut for the two last purposes, two or more crops may be had in a season from the same roots.

5520. The nutritive products of the principal herbage plants are thus given by Sir H. Davy:

SECTION I. The Clover Family. — Trifolium; Dianthella Decandria; and Leguminoseae J. Tréfle, Fr.; Klee, Ger.; Trifogli, It.; and Trebol, Span.

5521. The clovers (fig. 772.) are a numerous family, chiefly natives of Europe: those selected by the agriculturist are natives of Britain; and one species, the white or creeping clover, is often found in great luxuriance in native pastures. As ryegrass is very generally sown with clovers, it will be necessary to treat of its culture in connexion with these plants, reserving, however, the more particular consideration of ryegrass till we treat of the hay grasses. (Chap. VI.) Many intelligent cultivators consider ryegrass as a very severe crop for the soil; and it is alleged that wheat does not succeed well after the herbage with which ryegrass is intermixed in any considerable quantity. Other plants have accordingly been recommended as a substitute for ryegrass, and cock's-foot (Dactylis glomerata) has been tried, apparently with great success, by Coke of Holkham in Norfolk, and others; but this is a very coarse grass when allowed to rise to any height, and the use of it for hay has not yet been ascertainment. Donaldson considers the general introduction of clovers, and the cultivated grasses, as one of the greatest improvements in modern husbandry. The commencement of improvements in the different species of live-stock, in the modes of cultivation, and in the superior quality, as well as quantity, of the crops of grain, may all, he thinks, be dated from the period when the sowing of clovers and grass-seeds was first introduced into the different districts of the kingdom.
5522. The species of clover in cultivation are:—

5523. The red clover (Trifolium pratense, fig. 772. a), a biennial, and sometimes, especially on chalky soils, a triennial plant, known from the other species by its broad leaves, luxuriant growth, and reddish purple flowers. In its wild state a perennial.

5524. The white, or creeping, or Dutch clover (T. repens, b), a perennial plant, known by its creeping stems and white flowers.

5525. The yellow clover, hop-trefoil, or shamrock clover, the black mossuch of the Norfolk farmers (T. procerum, c), an annual, known by its prostrated shoots and yellow flowers. This species is seldom cultivated; the yellow clover of the seed shops being the Medicago lupulina, the lupine, or minette dorcé of the French. (fig. 772.)

5526. The meadow clover, cow-clover, cow-grass, or marsh-grass, the first the best name (T. medium, d), a perennial, resembling the red clover, but of a paler hue, dwarfer habit, with pale red or whitish flowers, and long roots very sweet to the taste. This species is but partially cultivated, and it is extremely difficult to procure the seeds genuine. It comes into flower from twelve to fifteen days later than the common red clover, has a solid stalk, a narrower leaf, and both leaves and flowers have a paler hue. A poor sandy soil, it is said, will produce a good crop of cow-clover that would not produce half a crop of the common red clover; it is also as good the second year as the first. Some farmers sow it because the crop comes in between the first and second cutting of the red clover as green food.

5527. The flesh-coloured clover (Trifolium incarnatum Lin.; Farouchè or Trefle de Roussillon, Fr. fig. 774.) has long been cultivated in some of the southern departments of France, and, though an annual, is found very advantageous on dry sandy soils. The Agricultural Society of Nancy have lately recommended it for culture in the province of Lorraine; and a writer in the Journal des Pays-Bas, as suitable to many parts of the Netherlands. M. de Dombasle, a theoretical and practical agriculturist in great estimation, sows it, after harvest, in the stubbles, with no other culture than harrowing in. It grows all the winter, and early in spring affords abundant food for sheep; or, if left till May, it presents a heavy crop for the scythe, and may be used for soiling, or making into hay. (Gard. Mag. iv. p. 392. and vol. v. p. 734.) It was introduced into England about the year 1824, by Mr. John Ellman, jun. of Southover, near Lewes, who gives directions for sowing it in March without a corn crop, and states that it will be in full bloom and fit to cut by June. He says it is very productive; but should not be sown with corns like other clovers, because it grows so fast as to choke them. (Farm. Jour. March 17. 1828.)

5528. Trifolium Molini, filiforme (with yellow flowers), campêtre (also with yellow flowers), and fragiferum, are cultivated in France; but we believe chiefly on the poorer soils. Seeds of them and of all the other species may be correctly obtained from Victorin Andreux and Co., seed merchants in Paris.

5529. In the choice of sorts the red or broad clover is the kind most generally cultivated on land that carries corn and herbage crops alternately, as it yields the largest produce for one crop of all the sorts. White and yellow clover are seldom sown with it, unless when several years' pasturage is intended.

5530. The soil best adapted for clover is a deep sandy loam, which is favourable to its long tap-roots; but it will grow in any soil, provided it be dry. So congenial is calcareous matters to clovers, that the mere strewing of lime on some soils will call into action clover-seeds, which it would appear have lain dormant for ages. At least this appears the most obvious way of accounting for the well known appearance of white clover in such cases.

5531. The climate most suitable for the clovers is one neither very hot nor very dry and cold. Most leguminous plants delight both in a dry soil and climate, and warm
5532. The preparation of the soil and the manures, which clover receives in ordinary farm culture, are those destined also for another crop; clover mixed with a certain proportion of rye-grass being generally sown along with or among corn crops, and especially with spring-sown wheat, barley, and the early varieties of oats. Unless, however, the soils on which these crops are sown are well pulv erised, and have been some years under tillage, clovers will not succeed in them, it being ascertained that newly broken-up leys or pasture grounds cannot be sown down or restored to clover and grasses till the soil is thoroughly comminuted, and the roots of the former grasses and herbage plants completely destroyed.

5533. The time of sowing clover-seeds is generally the spring, during the corn seed time, or from February to May; but they may also be sown from August to October, and when they are sown by themselves, that is, unaccompanied by any corn crop, this will be found the best season, as the young plants are less liable to be dried up and impeded in their progress by the sun, than when sown alone in spring and remaining tender and unshaded during the hot and dry weather of July.

5534. Some prepare the seed for sowing by steeping in water or in oil, as in Switzerland, and then mixing it with a previous antiseptic for the attack of insects.

5535. The manner of sowing is almost always broadcast. When sown with spring corn, clover and grass-seeds are usually put in immediately after the land has been pulverised by harrowing in the corn seed, and are themselves covered by the first portion of the harrowed or even of the harrow. But if the land is hoed in the fall, then the rye-grass, though the clovers and rye-grass are still sown in spring, the proper period must depend both upon the state of the land and the progress of the crops; and it may be often advisable to break the crust formed on the surface of tenacious soils, by using the harrow before the clovers are sown, as well as after wards to cover them.

Sometimes the roller only is employed at this time, and there are instances of clover and rye-grass succeeding when sown, without either harrowing or rolling. But it is commonly of advantage to the wheat crop itself, to use the harrows in spring, and the roller alone cannot be depended on, unless the season is very favourable. In some cases grass-seeds are sown by themselves, other in autumn or spring, but rarely on tillage land. Nature has not determined any precise depth for the seed of red clover more than other seed. It will grow vigorously from two inches deep, and it will grow when barely covered; but it may be recommended in clayey soil, or where there is what is light or loose. It is a vulgar error, that small seed ought to be sparingly covered. Misled by that error, farmers commonly cover their clover seed with a bushy branch of thorn; which not only covers it unequally, but leaves part on the surface to wither in the air.

5536. In the operation of sowing some consider it best to sow the clover and rye-grass separately; alleging that the weight of the one seed, and lightness of the other, are unfavourable to an equal distribution of both.

5537. The quantity of seed sown on an acre is exceedingly various; not only when more or less white or yellow clover is sown along with grass-seeds and red clover, or when pastureage is intended; but, even when they are the only kinds sown, the quantity is varied by the quality of the soils, and the different purposes of hay, sowing, or one year's pasture, to which the crop is to be applied. When pasture is the object, more seed is generally sown than is necessary when the crop is to cut green for feeding; and for hay, less may suffice than for either of the former. Finely pulv erised soils do not require so much seed as clay, on which clover and rye-grass are very frequently sown among autumn or winter-sown wheat, when there is more danger of their being imperfectly covered. When sown in the spring, and at the rate of from ten to twenty pounds to an acre, the former species may be taken as the minimum quantity, though there have been instances of good crops from less, and from that to fourteen pounds or more per English statute acre. Rye-grass, commonly at the rate of a bushel per acre, but in many cases only half, or two thirds of a bushel, is mixed with this weight of clover, and both are sown at the same time. The rye-grass may be either of the perennial or annual variety, as it is understood that the herbage is to be continued for only one year; and the annual is sometimes sown in preference, as producing a bulkier crop than the perennial.

5538. When it is intended to retain the latter in pasture for several years, the quantity of red clover is diminished, and several kinds of more permanent herbage are added, the most common of which are white and yellow clover, and ribwort. No general rule can be laid down as to the proper quantity of each of these kinds; in some cases red and white clover are sown in equal proportions, and in others the latter is made up to the amount of six parts, but where white clover and ribwort are not often sown at the rate of more than two or three pounds per acre. It is scarcely necessary to add, that, in this case, the rye-grass should always be of the perennial sort.

5539. In the selection of clover and rye-grass seeds particular attention should be paid to their quality and cleanliness; the purple colour of the clover seed denotes that it has been ripe and well saved; and the seeds of weeds may be detected in it by narrow inspection, if there are any; but various noxious weeds are frequently mixed up with the seeds of the rye-grass, which is difficult either to discover or separate from them. Between the seeds of the annual and perennial rye-grass the difference is hardly discernible; and therefore, unless it is of its own growth, the cultivator must depend in a great measure on the character of the person from whom he purchases it. Red clover from Holland or France has been found to vary much, but when it has been carefully pastured, with the latter clover, it produces plants which stand the second, many of them the third, year (General Report of Scotland, vol. i. p. 567.); thus remaining in the latter case four summers in the ground from the time of sowing.

5540. The after-culture of clover and rye-grass consists chiefly of picking off any stones or other hard bodies which may appear on the surface in the spring succeeding that in which it was sown, and cutting out by the roots any thistles, docks, or other large grown weeds. After this the surface should be rolled once to smooth it for the scythe. This operation is best performed in the first dry weather of March. Some give a top-dressing of soot, gipsy, common lime, peat, or wood-ashses, at this time or earlier.
gypsum has been particularly recommended as a top-dressing for clovers, and the other herbage legumes; because as their ashes afford that substance in considerable quantities, it appears to be a necessary ingredient of their food. Dutch ashes (427.) have been strongly recommended as a top-dressing for red clover, and they also contain gypsum; but where the soil is in good heart, and contains calcareous matter, any description of top-dressing, though it may be of advantage when it does not interfere with the general economy of the farm, cannot be considered necessary. (Supp. E. Brit. art. Agr.)

5541. The taking of the clover, or clover and rye-grass crop, is either by cutting green for soiling, by making into hay, or by pasturing. It is observed in The Code of Agriculture, that it is a most important point to ascertain in what cases cutting, or feeding, is more beneficial. If fed, the land has the advantage of the dung and urine of the pasturing stock; but the dung being dropped in irregular quantities, and in the heat of summer, when it is devoured by insects, loses much of its utility. If the dung arising from the herbage, whether consumed in soiling, or as hay, were applied to the land, in one body, and at the proper season, the operation would be more effectual. The snother of a thick crop, continued for any time upon the ground, greatly tends to promote its fertility; and it has been pretty uniformly found, after repeated trials, upon soils of almost every description, that oats or any other crop taken after clover that has been cut, either for soiling or hay, is superior to the crop taken after clover pastured by sheep.

5542. Soiling is a term applied to the practice of cutting herbage crops green for feeding or fattening live stock. On all farms, under correct management, a part of this crop is cut green, for the working horses, often for milk cows, and in some cases for beef cattle, and the grass, both for green and for swath pastures, both for green and for swath pasturing, is cut uniformly for the advantage of this practice, in regard to horses and cows; but for young and for fattening beasts, a sufficient number of experiments are not known to have been yet made with any great degree of accuracy. Young animals require exercise in the open air, and, probably, will not be fattened so well by the different feeds, both for green and for swath pasturing, as they would be, through in every case there is a great saving of food, the long, woody, and comparatively naked stems of the plants, with leaves always more or less withered, are perhaps not so valuable in the production of beef on fattening stock as a much smaller weight of herbage, which is not so unpalatable, that they may be feeding them, at least for a part of the day, in warm weather, ought to be more generally adopted; and the convenience of having working horses always at hand, besides that they fill their stomachs quickly, is of not less importance than economy. (See Communications to the Board of Agriculture, vol. vii. Brown's Treatise on Rural Affairs, vol. ii. General Report of Scotland, vols. ii. and iii.)

5543. In feeding cattle with green clover, attention must be paid to prevent swelling, or hoving, which is very apt to take place when they are first put on this food, especially if it is wet with rain or dew; and cattle are exposed to this danger, whether they are sent to depasture the clover, or have it cut and brought home to them; though, if the plants are somewhat luxuriant, the danger is greater in the former case. After being accustomed to this rich food for a few days, during which time it should be green, and the clover is unconnected; the danger is much diminished; but it is never safe to allow milk cows, in particular, to eat large quantities of wet clover.

5544. The making herbage plants into hay is a process somewhat different from that of making hay from natural grasses. All the herbage tribe ought to be mown before the seed is formed, and indeed before the plants have fully blossomed, that the full juice and nourishment of the herb may be retained in the hay. By the adoption of this system, the hay is cut in a better season, it can be more easily secured, and it is much more valuable. Nor is the strength of the plant lodged in the grain, as it is, when grown to hay, in the grass into hay is now beginning to be known. There is much more sacarce matter in it, and it is consequently greatly more nutritious. A crop of clover or sainfoin, when cut in the early part of the season, may be ten per cent. lighter than when it is fully ripe; but the hay is simply equivalent, or more, to one hay article; while the next crop will be proportionately more heavy. The hay made from old herbage which has ripened its seed will carry on stock, but it is only hay from herbage cut when young, and soon after it has come into flower, that will fattate the sheep when the stock is kept in close quarters; sometimes their seed towards its maturity, they are of little more value as provender than an equal quantity of the finer straw of corn.

5545. The mode of making clover-hay, and of that of all herbage-leaves, as practised by the best farmers, is as follows:—The herbage is cut as close to the ground and in an even manner, and perfect a manner as possible with a sharp scythe. The surface having been in the preceding spring freed from stones and well rolled, the stubble after the mower ought to be as short and smooth as a well shave grass-lawn. The part of the stems left by the scythe is not only lust, but the after-growth is neither so vigorous nor so weighty, as when the first cutting is taken as low as possible.

5546. As soon as the swath or row of cut herbage is thoroughly dry above, it is gently turned over (not tedded or scattered) without breaking it. Sometimes this is done with the hand, or with a small fork; and when it is too dry, as the wind may be too dry, the swath is made dry by spreading them out, or by planting it over the ridge of the rake shaft. The grass, when turned over, in the morning of a dry day, is put into cocks in the afternoon. The mode of performing this is very simple and expeditious; and none but women, girls, and inexperienced boys, who are not used to thev; are generally able to do it, but the heavy, a row of the cock, is put in the middle ridge of three, and if light of five ridges. A distinct company of carriers and rakers is allotted to every such number of ridges; and the separate companies proceed each on its own ground, and in the same manner as in reaping grain, which occasions a degree of competition among the different parties for the fashion, clean raking, and next well-built cocks. The carriers gather the hay, and carry it to the ridge where the cock is to be built by one of the most experienced hands. A raker follows the carrier, taking up and bringing to the cocks the remains of the swath. There may be, in general, about five people employed about each row of cocks; three carriers, two rakers on each end, and one person on the ridge, who builds them. But when the crop is not weighty, more rakers are required, as a greater space must be gone over.

5547. As the cocks are thus placed in a line, it is easy to put two or more into one afterwards; and the land may be speedily dryed, and be put into tramp-ricks, by means of ropes thrown round their bottoms, and dragged along by a horse. It is impossible to lay down any rules for the management of hay, after it is put into cocks; one thing is, however, always attended to, not to shake out, scatter, or expose the hay more than is necessary for its preservation. Sometimes the herbage is too large, that they never require to go to a tramp-rick, but are carted to the stack-yard, without ever being broken, and put up in alternate layers with old hay. But where this is attempted, there must not be much closer. The practice of mixing the new with the old hay is, however, a good one, and saves a great deal of time and labour, at the same time that the old hay is much improved by the mixture.
634. The making of clover hay, as practised in Cornwall, and adopted from that country in Silesia, is said to save not only a number of hands, but the hay is better and more nourishing. The hay is prepared by fermentation, whereby it retains its nutritious juices, and only loses its watery particles; it is dried by fermentation, whereas the hay is dried by haying, and thus its nutritious juices are concentrated. The process is conducted by the circulation of the liquid juices by heat, and the superabundant humidity is excluded, the sap-vessels are expanded by the heat, and thus future intestine fermentation is prevented, and the nutritious quality is preserved.

635. Clover intended for hay, after having been mowed, remains till four o'clock in the afternoon of the same day, or in a day and a half, if the weather is dry, in large cocks in the form of a sugar-loaf, and such a form is necessary, as free from defects, as possible. To prevent the air from entering, and washing away, and losing the heat of the hay, the cock must, whilst forming, be covered with a small sheet; when the fermentation is begun, the cock will, on being opened, smoke, or smell of brown-h, and may then be spread abroad. If in the morning, the hay is after the rain, or a little wind arises, the clover-hay will quickly dry; it is in the rain, because the rain will prevent the evaporation, though it may be turned with the rake or pitch-tork, and about four in the afternoon, it is not dangerous to put any danger of a second fermentation, so that it may be immediately carried into the barn; otherwise the cock will not be turned over, until three days, from the time of mowing. By this method of handling, and stretching, and very little work; whilst, in the common way, even in good weather, not a blade, but the cock may be put together in six or eight days. In the old method it frequently becomes of a bad house, and wet, and unchangeable in the barn. The method in which it is only brown, has an agreeable smell, and remains good and unchangeable in the barn. The farmer has also another hay, the hay, with the loose straw, which he makes not enough to carry it into the barn, he need only, if it be very dry, or in the winter stack, and never dried into the barn, but is dried in a dry, or in a very dry weather, and adopted in the same manner as the preceding part, after which it may be spread to dry, and brought into the barn.

636. Rule second. In such cases where a small portion of the cock has fermented thoroughly, but not the greater part, the heap must be spread abroad in the morning, or must be made up again to the top or outside of the cock, and this has not fermented must be again carried into the barn, and the clover treated in the same manner as above mentioned.

637. Rule third. If, in spreading the heap abroad, it is found that nearly the whole of the clovercock has fermented, and the weather so cold, that the hay cannot be dried, it must be turned over, and made into a new heap, and the remaining clovercock is to be carried into the barn, and fermented in the same manner as above, and when it becomes heated in any considerable degree, in the stack, though a slight combustion, with a kind of hay to become heated in any considerable degree, it is not advisable to allow this to happen for a considerable length of time. (General Report of Scotland, 1844.)
very gentle warmth, is usually perceptible, both in the field-ricks and in the stacks, for a few days after they are mown. But this is a quite different thing from that intentional heating, carried so far, in many instances, as to terminate in conflagration. 5558. The after-growth or second crop of clover is vigorous or weak, according to the proportion of clover plants to rye-grass, in the time when the first crop was made, and the warmth and sunlight of the season. When the first cutting is made early for wintering, there will sometimes be three cuttings of the season. The first of these after-cuttings may be made into hay, and sometimes the second; but in general both are consumed by soiling or pasturing, unless in some dry warm districts, as Norfolk, and parts of Sussex, where the sheep may be expected. And the seed of the second or late-cropped crop is seldom made into hay, owing to the difficulty of getting it thoroughly dried at a late period of summer, when other more urgent operations usually employ all the labourers of a farm. If it is cut for this purpose, the best method of using it is to mix it up with straw, which will absorb a part of its juice, and so often cut green, as a part of the soiling system; or, where a sheep stock is kept, pastures by the old ewes, or other sorts, that are to be fattened the ensuing winter on turnips.

5559. In consuming clover and other herbage plants by pasturing, or eating down on the spot, three methods are practised: tethering, or free pasturing, and cutting for hay. 5560. Tethering may be considered a rude practice, and is chiefly confined to the north of Scotland and Ireland. In The Agricultural Report of Aberdeenshire it is stated, that there are some cases where the plough could not be practised, and the plowman has to make a profit of the profitless. In the case of tethering, however, for instance, they tether milk cows on their grass fields, in a regular and systematic method; moving each tether forward in a straight line, not one foot at a time, so as to prevent the cows from treading on the grass that is to be eaten; care being always taken to move the tether forward, like a person cutting clover with a scythe, from one end of the field to the other. In this way, a greater number of cows can be kept, on the same quantity of grass, than by any other plan; except where it grows high enough to be cut, and given them green in houses. In one instance, the system was carried to great perfection, by a gentleman who kept a few sheep upon longer tethers, following the cows. Sometimes, also, he tethered horses afterwards upon the same field, which prevented any possible waste; for the tufts of grass produced by the dung of one species of animal will be eaten by those of another kind without reluctance. This system was particularly calculated for the cow-feeders in Peterhead; as, from the smallness of their contents, the could not afford to keep servants to cut, or horses to carry home, the grass to their houses, to be consumed in a green state. (Code.)

5561. In hurrying off clovers or herbage crops, a portion of the field is enclosed by hurdles, in which sheep are kept, as the clover is consumed, the hurdles are sent forward, being in this way fed off. This practice is very extensively adopted at Holkham, and is peculiarly calculated for light and dry soils. Its advantages are, that the grass is more economically consumed; that the stock thrive better, having daily a fresh bite; and that the dung falls, being more concentrated, is more likely to be of use. 5562. In the common pasturing of clover, the stock are introduced into the field earlier than in tethering or hurrying, in order to avoid the loss that would be sustained by cattle or sheep treading ad libitum on tall herbage. Indeed, the principal advantage of pasturing clovers is, that sheep and lambs may be turned out more than on cloverless land. Some of the newly-grazed land of clover is taken for a month or six weeks, in the beginning of summer, and the field afterwards shut up for a crop of hay; but more frequently the red clovers are only mown. When white and yellow clovers are sown, the herbage is sometimes not mown at all, but pastured for three years or more; and sometimes a little red clover being sown along with these, a crop of hay is taken the first year.

5563. The produce of clover-hay, without any mixture of rye-grass, on the best soils is from two to three tons per acre, and in this state in the London market it generally sells 20 per cent. higher than meadow-hay, or clover and rye-grass mixed. The weight of hay from clover and rye-grass varies, according to the soil and the season, from one ton to three tons per English acre, as it is taken from the trump-ricks; but after being stacked, and kept till spring, the weight is found to be diminished twenty-five or thirty per cent.

5564. The value of clover and rye-grass hay, in comparison with the straw of beans or peas, may be in the proportion of three to two; and with the finest straw of corn crops, in the proportion of two to one. One acre of red or broad clover will go as far in feeding horses or black cattle as three of ordinary pasturage; and when it is cut occasionally, and given to them fresh, it will, probably, go still much farther, as no part of it is lost by being trodden down. With the exception of lucern, and the herbage of rich marshes, there is no crop by which so much stock can be supported as by clover. It may be profitably employed in fattening sheep in spring, and with this food they will soon be ready for the butcher. Afterwards, a crop of hay may be got, and two or three weeks after the hay has been taken off, sheep intended to be fattened on turnips may be turned in, and kept there, until the turnips are ready for them. 5565. The nutritive products of clovers will be found in the table. (5520.) 5566. The saving of clover seed is attended with considerable labour and difficulty. Clover will not perfect its seeds, if saved for that purpose early in the year; therefore it is necessary to take off the first growth either by feeding or with the scythe, and to depend for the seed on those heads that are produced in the autumn. Seced-clover turns out to good account in those years when the crops are not injured by the blight, which is often fatal to them, or by the rains in the autumn, which sometimes prove their destruction; for the time of harvesting this seed falling out late when rainy weather may be expected, renders it, on that account, very tedious. 5567. When the first crop is fed off, it is eaten till about the end of May, frequently by ewes and lambs; and this is continued to be an advantageous practice, because the pasture is early furnished, and the green feed is the chief value for stock in the spring months. It is not uncommon, however, to cut the first growth for a hay crop, and this should be done earlier than usual. The growth thus reserved for seed must be suffered to remain till the husks become perfectly dry, when it is cut and harvested in the usual manner. The field till covered with dry and dry crop, that the husks may be made thinner, it may then be laid up dry, to be threshed out at the farmer's convenience. Much labour and expense are necessary in separating the seed from the chaff or seed-dust, especially when it is effected by threshing, which seldom costs less than from five to six or seven shillings per bushel. By the use of mills the work may be done much cheaper.
5568. The management of a crop of clover with a view to saving seed is thus given by a cultivator in Buckinghamshire. A moderate bulk of haulm is generally found most productive of seed, and a moderately rich, sharp, dry soil is the best for having moderate haulm. The field may be pastured till the middle of May, and then shut up till the ripening is completed. August is generally the ripening month, and the maturity of the seed may be known by the leaves becoming dry and dropping off. Observing that the seed from time to time, and when it has changed from a bright yellow to a deep purple, it is then ready for the seythe. After the crop is cut down, disturb it as little as possible by fork or rake. Form it into small cocks not larger than much heaps. Should favourable weather ensue, nothing more is necessary than to turn these cocks once over, shortly before carting home. And should the weather prove fickle, these small heaps of withered straw are very soon dried, perhaps in one good day, by turning up the bottom, after the top has become a little dried. After remaining some time in the field, the cocks subside considerably and become caked, by which the flowers adhere together and repel the rain; of course, no less of top can be sustained by gently turning them to dry. It thus appears, that clover for seed is not so liable to be injured as clover for hay. In general six or ten days of favourable weather render it fit to carry to the rick-yard and stack. It may either be threshed by a light flail, or by threshing machines, having a particular additional cover introduced below the drum or beater for that purpose.

5569. In threshing, whether by the flail or machine, the first operation is to separate the heads or spikes of seeds from the haulm. This operation separates none of the seed, which remains firm in the withered florets, and requires to be repeated by the course of light threshing. The second operation is for hummeling barley. When on examination it is found that the seed is all separated, the operations of sitting and winnowing ought to be carried on in the usual manner with appropriate sieves; the clover sieve being well known to the sieve-maker. The average produce per acre is three hundred weight.

5570. Seed may be saved from a second crop; that is, after the first crop has been mown for hay; but the sample is seldom so strong or plump as that from a first crop.

5571. White clover, and also yellow clover, lucern, and saintfoin, when intended for seed, are treated much in the same manner as red clover. (Farm. Mag. vol. xix. p. 570.)

5572. The produce in seed may generally be from three to four or five bushels per acre, when perfectly clean, weighing from two to three hundred weight. But there is great uncertainty in the produce of clover seed, from the lateness of the season at which it becomes ripe; and the fertility of the soil is considerably impaired by such a crop. Yet the high value of the seed is a great inducement to the saving of it, in favourable situations. (Dickson’s Practical Agriculture, vol. ii. p. 863.)

5573. The diseases of clover are the blight or mildew, and suffocation or consumption, from insects, slugs, and worms. It often happens that clover, after being repeated at short intervals on the same soil, either fails or does no good; whether that is owing to a disease, or to a defect of some peculiar substance which enters into the food of the plant, does not appear to be clearly ascertained. A top-dressing with ashes or lime is said to be unfavourable to the slug; but where vermin of this sort are very numerous, the most certain remedy is a naked fallow well worked in the hottest months.

Sect. II. Lucern. — Medicago sativa L.; Diatelpith Decandria L., and Leguminosa J. La Lucerne, Fr.; Futterklee, Ger.; Medica, Ital.; and Micga Span. (fig. 775.)

5574. Lucern is a deep-rooting perennial plant, sending up numerous small and tall clover-like shoots, with blue or violet spikes of flowers. It is a native of the south of Europe, and appears to be acclimated in the warmer parts of England. Lucern or medic is highly extolled by the Roman writers, and also the cytisus, the latter a low evergreen shrub. Lucern is much grown in Persia and India, and mown in both countries all the year round; it is also of unknown antiquity in old Spain, Italy, and the south of France. It was introduced to England from the latter country, according to Miller, in 1637. It is mentioned by Hartlib, Blythe, and other early writers, and was tried by Lisle; but it excited little attention till after the publication of Harte’s Essays, in 1757. It is now only cultivated in a few places, and chiefly in Kent. Columella estimated lucern as the choicest of all fodder, because it lasted many years, and bore being cut down four, five, or six times a year. It enriches, he says, the land on which it grows, fattens the cattle fed with it, and is also a remedy for sick cattle. About three quarters of an acre of it is, he thinks, abundantly sufficient to feed three horses during the whole year.

5575. Clover has found no great reception in this country, though it was so much esteemed by the ancients, and has long been cultivated to advantage in France and Switzerland. It any good reason can be given for this, it is, that lucern is a less hardy plant than red clover, requires three or four years before it comes to its full growth, and is for these and other reasons ill adapted to enter into general rotations. Where the climate and soil suit, perhaps a field of it may be advantageously sown, adjoining the home-stall, to afford early cutting or food for young or sick animals, for which it is said to be well adapted; but though it will produce good crops for eight or ten years, yet from the time the farmer must wait till this crop attains perfection, and from the requisite to keep it free from grass and weeds, we do not think it is ever likely to come into general culture. The Highland Society have lately offered premiums for the culture of this plant in Scotland, and crops have been produced in dry sandy soil in the neighbour-hood of Edinburgh; the climate, however, and the alternate and compost of culture generally pursued in the northern parts of the island, and which seems so well adapted to its agricultural circumstances, forbid the hope that it can ever become general.
5576. There are no varieties of the lucern deserving the notice of a cultivator.

5577. What is called the yellow lucern is the Medicago sativa (Lucerne en famille, or Lucerne de Suede, Fr. Mt. Titi); a much harder and coarser plant, common in several parts of England, but not cultivated anywhere except in some parts in France and Southern Ireland.

5578. Medicago maculata and mariciata are cultivated in France, but to a very limited extent on poor soils. M. lupulina (lupine, or Muste dorée, Fr.) resembles our well known hop-trefol, black from its seeds) nonsuch, or yellow clover; but it is seldom cultivated in Britain.

5579. The soil for lucern must be dry, friable, inclining to sand, and with a subsoil equal to it in goodness. Unless the subsoil be good and deep, it is in vain to attempt to cultivate lucern. According to Young, the soils that suit lucern are all those that are at once dry and rich. If, says he, they possess these two criteria, there is no fear but they will produce large crops of lucern. A friable deep sandy loam on a chalk or white dry marly bottom is excellent for it. Deep putrid sand warp on a dry basis, good sandy loam on chalk, dry marl or gravel, all do well; and in a word, all soils that are good enough for wheat, and dry enough for turnips to be fed on the land, do well for lucern. If deficient in fertility, they may be made up by manuring, but he never yet met with any land too rich for it.

5580. The preparation of the soil consists in deep ploughing and minute pulverisation; and, in our opinion, the shortest way to effect this, is to trench it over by the spade to two or three feet in depth, burying a good coat of manure in the middle or at least one foot from the surface. This is the practice in Guernsey, where lucern is highly prized.

5581. The climate for lucern, as we have already hinted, must be warm and dry; it has been grown in Scotland and Ireland, and might probably do well in the southern counties of the latter country, but in the former it has not been found to answer the commendations of its admirers.

5582. The season most proper for sowing lucern is as early as practicable in the spring months, as in this way the plants may be fully established before the season becomes too hot. The latter end of March, for the more southern districts, may be the most proper period; and the beginning of the following month for those of the north. When sown late, there is more danger of the plants being destroyed by the fly, as it has been observed by Tull. If the plants are intended to be transplanted out in the garden method, it will also be the best practice to sow the seed-bed as early in the spring as the frosts will admit, in order that they may be strong, and fit to set out about the beginning of August.

5583. The manner of sowing lucern is either broadcast or in drills, and either with or without an accompanying crop of corn for the first year. Broadcast, with a very thin crop of barley or other spring corn, is generally, and in our opinion very properly, preferred. Arthur Young, who has treated largely on this plant, observes, that "the greatest success by far that has been known is by the broadcast method, which is nearly universal among the best lucern farmers, even among men who practise and admire the drill husbandry in many other articles. But as they mostly (not all) depend on severe harrowing for keeping their crops clean, which is a troublesome and expensive operation, he still ventures to recommend drilling; but very different drilling from that which has been almost universally practised, viz. at distances of eighteen inches or two feet. Objections to the wide intervals are numerous. If kept clean hoed, the lucern takes up so much dirt, being beaten to the earth by rain, etc. that it is unsightly, and the plants spread so into these spaces, that it must be reaped with a hook, which is a great and useless expense. For these reasons, as well as for superiority of crop, he recommences drilling at nine inches, which in point of produce, moving, and freedom from dirt, is the same as broad cast; and another advantage is, that it admits scarifying once a year, which is much more powerful and effectual than any harrowing. These facts are sufficient to weigh much with any reasonable man, as to induce him to adopt this mode of drilling, as nearer to broad-cast by far than it is to drills at eighteen to twenty-four inches, which open to a quite different system, and a set of very different evils. Nine-inch rows might practically, but not literally, be considered as broad-cast, but with less degree of scarifying. And in regard both to scarifying or without corn, two considerations, he says, present themselves. One is the extreme liability of lucern to be eaten by the fly, which does great mischief to many crops when very young, and against which the growing of corn is some protection. The value of the barley or oats is another object not to be forgotten. It is also gained in the first year's growth of the lucern, which is very poor producers even if no corn be sown; so that he must own himself clearly an advocate for drilling in among corn, either between the rows of nine-inch barley, or across the corn, at a foot, if perhaps the latter has the best method; and there is less probability of the crop being laid to the damage of the lucern. The quantity of seed-corn should also be small, proportioned to the richness of the land, from one bushel to a bushel and a half, according to the fertility of the soil; another security against the mischief of lodging. If those precautions are taken; it would be presumptions to say that success must follow, that being always, and in all things, in other hands than ours; seed may prove bad, the fly may eat and drought prevent vegetation; but barring such circumstances, the farmer may rest satisfied that he has done what can be done, and if he do succeed, the advantage will be unquestionable."

5584. The quantity of seed, when the broadcast method is adopted, is said to be from fifteen to twenty pounds per acre, and from eight to twelve if drilled. The seed is paler, larger, and dearer than that of clover; it is generally imported from Holland, and great care should be had to procure it plump and perfectly new, as two-years-
old seed does not come up freely. The same depth of covering as for clover will
answer.
Lucern may be transplanted, and when the soil is very rich and deep, it is said
to produce very large plants; but such plants, from the bulk of their stools, are not
likely to be so durable as those of a less size; and on the whole, for this reason and others
relative to expense, the plan of transplanting does not seem advisable unless for filling
up blanks.
The after-culture of lucern, sown broad-cast, consists in harrowing to destroy
grass and other weeds; rolling, after the harrowing, to smooth the soil for the slyte;
and such occasional top-dressings of manure as the state of the plants may seem to
require.
When lucern is drilled, horse-hoeing may be substituted for harrowing, which,
as already observed, is the only advantage of that mode of sowing. The harrowing
may commence the second year, and the weeds collected should always be carefully
removed: light harrows may be used at first, and in two or three years such as are
heavier. In succeeding years two harrowings may be required, one early in the spring,
and the other at the close of the summer. For these, and especially the last, Arthur
Young recommends the use of a harrow of weight sufficient for four horses, and which
does not cover a breadth of more than four feet. The mode of hoeing, either by the
hand or horse-hoe, or of stirring by the drill harrow, requires no description.
The top-dressings given to lucern may be either of the saline or mixed manures.
Aches are greatly esteemed, and also gypsum and liquid manure of any kind. Arthur
Young advises to apply dung, in the quantity of about twenty tons to the acre, every
five or six years. Kent, however, thinks it a better practice to put a slight coat on
annually in the spring season. Some recommend a slight top-dressing sown by hand
every spring. The farmer will in this, as in every case, exercise his own judgment, and
be guided by the wants of the plants, the return they yield for the expense bestowed on
them, and the equitable distribution of manure among his other crops.
The taking of lucern by mowing for silloing, or hay, or by tethering, hurdles,
or pasturing, may be considered the same as for clover. Lucern frequently attains a
sufficient growth for the slyte, towards the end of April, or beginning of the following
month; and, in soils that are favourable for its culture, will be in a state of readiness for
a second cutting in the course of a month or six weeks longer, being capable of under-
going the same operation, at nearly similar distances of time, during the whole of the
summer season. In this last sort of soil, with proper management, in the drill method,
it has been found to rise to the height of a foot and a half in about thirty or forty days,
affording five full cuttings in the summer. But in the broad-cast crops, in the opinion
of some, there are seldom so many cuttings afforded in the season, three or four being
more common, as the growth is supposed to be less rapid than by either of the other
modes.
The application of lucern is also the same as that of clover. The principal and
most advantageous practice is that of silloing horses, neat cattle, and hogs: but as a dry
fodder, it is also capable of affording much assistance: and, as an early food for ewes
and lambs, may be of great value in particular cases. All agree in extolling it as food
for cows, whether in a green or dried state. It is said to be much superior to clover, both
in increasing the milk and butter, and improving its flavour. In its use in a green state,
care is necessary not to give the animals too much at a time, especially when it is moist,
as they may be baven or blown with it, in the same way as with clover, and other green
food of luxuriant growth.
The produce of lucern, cut three times in a season, has been stated at from three
to five and even eight tons per acre. In silloing, one acre is sufficient for three or four
cows during the silloing season; and a quarter of an acre, if the soil be good, or half an
acre on a moderate soil, for all sorts of large stock, for the same period. Say, however,
that the produce is equal in bulk and value to a full crop of red clover, then, if continued
yearly for nine or ten years (its ordinary duration in a productive state), at an annual
expense of harrowing and rolling; and a triennial expense of top-dressing, it will be of
sufficient value to induce farmers, who have suitable soils and climates, to lay down a few
acres under this crop near their homesteads.
The nutritive product of lucern, according to Sir H. Davy, is 2 3/10 per cent., and
is to that of the clovers and sainfoin as 23 to 29. This result does not very well agree
with the superior nutritive powers attributed to lucern.
To save seed, the lucern may be treated precisely as the red clover, and it is
much more easily threshed, the grains being contained in small pods, which easily separa-
rate under the flail, or a threshing machine, or clover mill.
The diseases of lucern appear to be the same as those of clover. In Kent, blight
and the slugs are its greatest enemies.
Saintfoin. — Hedysarum Onobrychis L.; Diadelphe Decandrea L., and Leguminosae J. Bourgogne, or Esparrette, Fr.; Esparrette, Ger.; Cerdangola, Ital.; and Esparsita, Span. (fig. 777.)

5595. *Saintfoin* is a deep-rooting perennial with branching spreading stems, compound leaves, and showy red flowers. It is a native of England and many parts of Europe, but never found except on dry, warm, chalky soils, where it is of great duration. It has been long cultivated in France and other parts of the Continent, and as an agricultural plant was introduced from France to England about the middle of the seventeenth century. It has since been a good deal cultivated in the chalky districts; and its peculiar value is, that it may be grown on soil unfit for being constantly under tillage, and which would yield little under grass. This is owing to the long and descending roots of the saintfoin, which will penetrate and thrive in the fissures of rocky and chalky understrata. Its herbage is said to be equally suited for pasture and for hay, and that eaten green it is not apt to swell or have a battle like the clovers or lucern. Arthur Young says, that upon soils proper for this grass no farmer can sow too much of it; and in *The Code of Agriculture* it is said to be "one of the most valuable herbage plants we owe to the bounty of Providence."

5596. *There are no varieties of the saintfoin in England, but many other species of the same numerous family might be cultivated, such, for example, as the French honey-suckle, a biennial that might be substituted for red clover on rich soils. The French have a variety which they call *Saintfoin à deux coups*, and they also cultivated the *Saintfoin d'Espagne* or *Saltia*.*

5597. The best soil for this plant is that which is dry, deep, and calcareous; but it will grow on any soil that has a dry subsoil. Kent thinks that the soils most suited to the culture of this sort of grass are of the chalky loam and light sandy or gravelly kinds, or almost any of those of a mixed quality, provided they are sufficiently dry, and have a rocky or hard calcareous bottom to check the roots at the depth of a foot or fifteen inches below the surface, which he conceives necessary, as the plants are apt to exhaust themselves in running down; and for this reason he considers it improper for being sown where there is great depth of mould or soil. It is a plant that is asserted by Marshal to afford a large produce even on those soils which are of the poorest quality, and on such as are of a more rich and friable nature to frequently produce abundant crops. Still, he conceives, that it is only in the calcareous soils, as the dry chalk and limestone, or such as have been well impregnated with that matter, that it succeeds in a perfect manner or becomes durable. The advantages resulting from growing this plant on sandy soils in Norfolk have been already stated. (4744.)

5598. *The best preparation which any soil fit for this plant can undergo is, unquestionably, trenching; and if there have little doubt that in most cases, all things considered, it would be found the cheapest. The usual preparatory culture, however, is to plough as for clover, ploughing more deeply than ordinary, either by means of the trench plough, or, what is better because more simple, by the common plough going twice in the same track. Boys (Communications to the Board of Agriculture, vol. iii.) recommends as a preparation for saintfoin: 1st year, pare and burn for turnips, to be eaten on the land by sheep, with the aid of some fodder; 2d, barley, to be sown very early with clover seed; 3d, clover eaten off by sheep; 4th, wheat; 5th, turnips with manure; and, 6th, barley with saintfoin. The corn crops must be carefully weeded, and in particular cleared of charlock. Under this system, the produce has been great, and the ground has been laid down in the highest order with saintfoin, or any other grass calculated for this species of soil.*

5599. *With respect to the season of sowing saintfoin, it may be observed, that the earlier it can be put into the soil in the spring the better, as from the greater moisture of such soils there will be a greater probability of its vegetating in a perfect manner. Where the sowing is executed at a late period, and dry weather succeeds, Bannister thinks that much of the seed is prevented from growing, and that the young plants are more exposed to destruction from the fly; therefore, according to this writer, the sowing of saintfoin seed ought never to be deferred longer than the beginning of March, and it is still better to complete this work in February. Some, however, suppose it may be deferred to the middle of March without injury, and this is soon enough if it is to be sown with barley.*

5600. *The manner of sowing is generally broadcast; but it may be sown in drills and even transplanted, though neither of these modes can be recommended. Some advise its being sown with about half the quantity of barley usually sown for a full crop, which may shade and keep it moister during the first summer, and at the same time not injure it from the crop being lighter, which is sometimes the case. Where the barley is drilled, the saintfoin may afterwards be put in, in the same manner, but in a contrary direction. If sown over the wheat, it should be harrowed in, and afterwards rolled. In whatever method it is sown, as the seeds are larger than those of many other herbage plants, they should be covered in with more care, and to a somewhat greater depth. By some the ploughing of the seed in with a very thin or shallow
farrow is recommended. In most cases, especially in all the more light sorts of land in which this sort of crop is grown, the use of the roller may be necessary immediately after the seed is put into the ground. It is the practice in a portion of eastern England, with small plots of saintfoin, with the idea of increasing the first year's produce; but as plants of different kinds seldom answer well when grown together, from being a continual contest in their growth for an ascendency, it is perhaps a better method to increase the proportion of the seed, without mixing it with that of other sorts. It is, however, suggested that this practice is in ultimate perfection, when the density of a first-year field, by sowing a small and well-drilled proportion upon the land. It is a sort of crop that grows in so perfect a manner in the broad-cast method, that there can seldom be any necessity for having recourse to the drill. It may, however, be cultivated in the latter mode of practice with success to the product of the planters who have it drilled at nine inches across the barley crops which have been sown in the same way.

5591. The quantity of seed in the broad-cast method, which is that mostly employed, is about four bushels the acre, though less is frequently given; but on such soils as are proper for this plant it is always noted, they make a good proportion of the rows of the plants, and where the drill system has had recourse to, a still smaller proportion is used, as from two to two and a half or three bushels. It has been observed, that in Lincolnshire, where this plant is much grown, "the common practice is five bushels to an acre, and that a gentleman south of Lincoln advises the sowing a small quantity of trefoil with it (about four pounds on an acre)." The reason for this is, that in that exposed country, the young plants suffer more by the sun in summer than by the frost in winter. Of course the trefoil coming to perfection the first year, and living only three, will be a shelter for the young plants of the latter year, two or three, and die off when the saintfoin wants its room.

5592. In the choice of the seed the safest practice for the cultivator is to select it from the best and most abiding plants in this particular soil, as that purchased from the seed-shops can rarely be depended upon. A right method of knowing the goodness of the seed is, by sowing a number of the seeds, and seeing how many plants are produced by them. But the external signs of the seeds being good are, that the husk is of a bright colour, and the kernel plum, of a light grey or blue colour, and sometimes of a shining black. The seed may be good, though the husk be black, as that is owing sometimes to having been heated in the heat. If the kernel on being cut across appears greenish and fresh, it is a certain sign that it is good; but if it is of a yellowish colour, and friable, and looks thin and pitted, it is a bad sign. Others observe that the best seed is plum, heavy, bright, and of a yellowish red colour, and that it should always be sown while quite fresh, as old seed, or seed that has been long kept, never vegetates in a perfect manner; seed of this sort is in general from about three to five shillings the bushel.

5603. The after-culture and management of saintfoin consists in occasional dressings with manure, and, in the judicious intervention of mowing and pasturing.

5594. Some farmers do not sow in the first year, while others do; in the second year, and in the succeeding summers, a crop of hay may be taken, and the after-grass fed down with any sorts of stock but sheep, till towards December. These should not be permitted to get too close, as, from the largeness of the roots, they might make a full proportion of the rows of the plants. In the following season there will, however, be less risk in this respect, and sheep as well as cattle may be turned in and kept upon the pastures till they are well eaten down, being always careful to shut them up as early as possible in the beginning of autumn, in order to prevent the loss of the root. As this practice is seldom attended to, and the risk is thereby increased, and possibly being nipped by the frost, it may be a proper practice not to turn stock upon these leys too early in the autumn season; perhaps not before the latter end of September, when this sort of root or after-grass will be found to have much effect in promoting the digestion of milk and flesh, as well as in forwarding the process of vegetation still being left for sheep. But with this sort of stock they should not be too closely fed down, nor should the sheep remain too long upon them. It has been suggested that all sorts of cattle seed should be removed by the beginning of the year from these leys, as much harm may be done by them continuing to graze them in this state.

5595. In top-dressing saintfoin peat ashes are the best material that can be made use of where they can be procured in sufficient quantity; and other sorts of ashes are likewise found beneficial where these cannot be had. They should be applied so as to form a thin, even dressing, and, from the largeness of the roots, it requires the least pains in making. When the season is favourable, the hay-makers may follow the scythe, and having turned over the swaths, throw them into wind-rows the succeeding day after the crop is mown, when it may be immediately forced into cocks, and the practised hand can have them fit for carting with the least possible loss. In this view the saintfoin is supposed to be of great utility when spread evenly over such leys about the beginning of January, in the proportion of about twenty-five or thirty bushels to the statute acre; and malt-dust has been employed in the same way with great success and advantage, as shown by Bannister. It is also supposed that when the grain is sown, the grass can be applied every third or fourth year, the saintfoin crops, when well established in the soils, may be preserved in a state of vigorous growth for ten or fifteen years, or more, and the land be considerably improved by the roots striking so deeply into it.

5606. In taking and using the saintfoin crop, the same practices may be followed as in taking clover: it may be mown for soiling, hay, or seed; and eaten on the spot by tethering, hurling, or common pasturing.

5597. In making it into hay, it is cut immediately on its coming into full blossom, and as it remains but a short time in this state, as much expedition as possible should be employed both in mowing and making the produce into hay. It is remarked by the author of The Synopsis of Husbandry, who resides in a district where the culture of saintfoin is frequent, that all other hay plants, it requires the least pains in making. When the season is favourable, the hay-makers may follow the scythe, and having turned over the swaths, throw them into wind-rows the succeeding day after the crop is mown, when it may be immediately forced into cocks, and the practised hand can have them fit for carting with the least possible loss. In this view the saintfoin is supposed to be of great utility when spread evenly over such leys about the beginning of January, in the proportion of about twenty-five or thirty bushels to the statute acre; and malt-dust has been employed in the same way with great success and advantage, as shown by Bannister. It is also supposed that when the grain is sown, the grass can be applied every third or fourth year, the saintfoin crops, when well established in the soils, may be preserved in a state of vigorous growth for ten or fifteen years, or more, and the land be considerably improved by the roots striking so deeply into it.

5598. In regard to the frequent cutting of saintfoin, it is probable that on the thinner soils it can seldom be done more than once; but those of a heavier soil where more dressings are taken, in the same manner as with clover, care being taken in these cases that the future growth of the plants be not injured by this means.

5599. The usual duration of saintfoin, in a profitable state, is from eight to ten years. It attains its perfect growth in about three years, and begins to decline towards the eighth
or tenth on calcareous soils, and about the seventh and eighth on gravels. There are instances, however, of fields of saintfoin, which had been neglected and left to run into pasture, in which plants have been found upwards of fifty years from the time of sowing. It has been cultivated upwards of a century on the Cotswold Hills, and there roots of it have been traced down into stone quarries from ten to twenty feet in length, and in Germany von Thaer found them attain the length of sixteen feet. In general the great enemy to the endurance of saintfoin is the grass, which accumulates and forms a close turf on the surface, and thus chokes up the plant.

5610. The quantity of produce in the state of hay, on a medium of soils and cultivation, may probably be estimated at from about one and a half to two tons the acre; and on the poorer and thinner staple sorts of land it will, perhaps, seldom afford less than from a ton to a ton and a half on the acre.

5611. The nutritive products of saintfoin are the same as clover; viz. $2^{11\over 3}$ per cent more than those of lucerne.

5612. In saving seed from saintfoin, it should remain on the land till the husks become of a somewhat brownish colour, and the seeds are perfectly plump and firm; as by these means they will not only be better in their quality, but be in less danger of being injured in the field, from the very short time that it will be necessary for them to remain, and also less in danger of being hurt by heating when laid up for future use. It has been stated, that it requires some experience to know of what degree of ripeness it is best to cut the seeded saintfoin, because all its seeds do not ripen at the same time. Some ears blossom before others; and every ear begins to blossom at its lower part, and continues to blow gradually upwards for many days; so that before the flower is gone off at the top, the seeds are almost mature at the bottom. From this cause, if the cutting be deferred till the top-seeds are quite ripe, the lower, which are the best, would shed and be lost.

5613. The best time to cut it is when the greater part of the seed is well filled, the first blown ripe, and the last blown beginning to be full. The unripe seeds will ripen after cutting, and be in all respects as good as those that were ripe before. Some, for want of observing this, have suffered their saintfoin seed to stand till all of it is shed, and been lost in cutting. Saintfoin seed that never can be cut in the heat of the day, while the sun shines out for too much, even of the unripe seed, will shed in mowing. The right time for this work is the morning or evening, when the dew has rendered the plants supple. When the weather is fine and clear, the saintfoin will soon dry sufficiently in the swaths, without turning them; but if any rain falls, and there is a necessity for turning them, it should be done very gently while they are moist, and not with two swaths together, as in hay made of saintfoin before it has seeded. If the swaths are turned with the handle of the rake, it is best to raise up the edge sides first, and let the stub-side rest on the ground in turning; but if it is done with the teeth of the rake, let the stub-side be lifted up, and the ears rested on the earth. If it be cocked at all, the sooner it is done the better; because, if the swaths are dry, much of the seed will be lost in separating them, the ears being entangled together. When moist, the seeds stick fast in the ear; but when dry, they drop out with the least touch or shaking. It is, however, the best practice, as soon as the proper degree of maturity has been attained by the crop, to mow it in as short a time as possible, and let it remain exposed in the swath until the upper surface is fully dried, when it must be wholly turned over, but in a very careful manner, so as to prevent the seeds from shedding and becoming lost. When this time has been rendered perfectly dry, the seeds will be in the same way as the other, cut off, threshed out and thrashed out on coarse cloths in the field where it is grown, or laid up in stacks to be afterwards threshed when the farmer has more leisure and convenience for the work.

5614. The work of threshing out the seeds in this kind of crop is much less troublesome and expensive than in the clover kind. In cases where threshing-machines are in use, the business may be executed by them with great ease and facility. It has, however, been observed by a late writer, that "when the season is favourable, the practice of threshing it out in the field is probably the most beneficial, as the stems or haulm may be laid up for the purpose of fodder in the stack."

5615. As the threshing in the field cannot be done but in very fine weather, and while the sun shines in the middle of the day, the best manner of performing it is to have a large sheet pegged down to the ground for, we used to thresh on with their flails, while two others bring them fresh supplies in a smaller sheet, and two more away the hay that has been threshed. The seed is emptied out of the larger sheet, and riddled through a large sieve, to separate it from the chaff and broken stalks; after which it is to be carried into a distant barn, and not be allowed to be wet until it reaches the barn, and is then dried, as in that case it would be spoiled. It is a very important, but difficult matter, to keep the seed that has been threshed in the field from becoming wet. If it be winnowed immediately, and laid in a heap on a barn-floor, it will ferment to such a degree in a few days that the greater part of it will lose its vegetative quality. During that fermentation it will be very hot, and smell sour. Spreading it upon a barn-floor, though seven or eight inches thick, will answer no end, unless it be frequently and regularly turned until the heating is over; but even this will not make its colour keep so bright as if it were wholly fresh, dry, and threshed in the winter. Laid up unthreshed it will keep without any danger of spoiling, because it does not lie close enough to heat. The best way to preserve the seed threshed in the field is to place a layer of straw upon a barn-floor, and upon that a thin layer of seed; and another layer of straw, and so on, until the heap of seed; mixing with the straw, will be kept well, and come out in the spring as fresh colour as when it was put in.

5616. In respect to the produce in seed, it is said to be usually "from about four to five sacks in some districts, but in others it will probably be much less, especially on the shallower sorts of saintfoin soils." But this must obviously be liable to great variation from seasons, &c.

5617. The diseases of saintfoin are few, there being little danger of failure after it has escaped the fly; which attacks the clover tribe in germinating.
SECT. IV. Various Plants (not Granimose) which are or may be cultivated as Herbage and for Hay.

5618. Among the inferior herbage plants which are occasionally cultivated, are burnet, ribwort, furze, and spurry. Those which might be cultivated are very numerous, and includes several species of Vicia, Lathyrus, Galéga, Lotus, Trifolium, Medicago, and others of the native Leguminose, or pea-like flowering plants; and Achillea, Alchemilla, Cheiranthus, Spartium, Atripium, and a variety of others of different families. With the exception of the chicory and furze, there are none of these plants that deserve the attention of the professional farmer; ribwort and burnet are occasionally sown; but they are of little value as hay plants, and in most pastures their place might be more advantageously occupied by one or other of the natural grasses. With respect to the other plants enumerated, they have never been tried but by way of experiment, and are only mentioned as resources under peculiar circumstances, and as a field of enquiry and exertion for the amateur cultivator.

5619. The burnet (Pimprenelle grande, Fr.; Poterium Sanguisorba L., fig. 778.) is a native plant, a hardy perennial with compound leaves, blood coloured flowers, and a long tap-root. It was originally brought into notice by Roque, a commercial gardener, at Waltham green, near London, who found means to procure the patronage of the Dublin and other societies to this plant, which, being a novelty, attracted the attention and called forth the reports of Arthus Young, and other leading agriculturalists. Dr. Miller, however, at the time observed, that whoever will give themselves the trouble to examine the grounds where it naturally grows, will find the plants left ungrazed by the cattle, whereas, when they have been cropped to the roots; besides, in wet winters and on strong land, the plants are of short duration, and therefore very unfit for the purpose of pasture or hay, nor is the produce sufficient to tempt and induce a spirit of skill to cultivate it.

5620. Curtis says of burnet, that it is one of those plants which has for some years past been attempted to introduce into agriculture; but in all cases answering the farmer's expectation, its produce is laid aside. Cattle are said not to be fond of it; nor is its produce sufficient to answer the expense attending its culture. It is to be lamented that persons do not pay a little attention to the nature of plants before they are warmed by the ardor of experiment. A small plant, scarcely ever met with on hilly and chalky ground, and to which cattle in such situations do not show any particular attachment, is not likely to afford better or more copious nourishment than the clovers and other plants already in use.

5621. According to Boys, in The Agricultural Survey of Kent, it affords herbage in the winter and spring months, but is not much liked either by cattle or sheep. It is a bushel of seed is commonly sown in an acre.

5622. Dr. Anderson reports, that burnet retains its verdure pretty well during the winter months, but affords such scanty crops as hardly to be worth the attention of the farmer.

5623. A correspondent in the Museum Riddellum, a work very favourable to burnet, confesses with reluctance that it is not deserving of any exalted character, but rather the contrary; and that it is in no degree to be compared to the common clover, which is cultivated at half the expense. It appears from some accounts that horses will not eat it at all, and that kine frequently will not take it without great reluctance. Its slow growth is a great objection, as it makes a great only of a short period, and having scarcely one head in flower; whilst lucern, on the same soil, sown the same day and much thicker, was eighteen or twenty inches in height. It is not meant by this, however, to discourage that laudable spirit of improvement which so happily prevails at present; but to caution such as introduce any new plant to make themselves well acquainted with its natural history.

5624. Those who wish to cultivate burnet, as an herbage and hay plant, may treat it exactly as directed for saufiton; as a pasture plant it is sown among the grasses in the same way as white or yellow clover. A bushel of seed is commonly sown in an acre.

5625. The ribwort plantain (Plantain des Prés, Fr.; Plantago lanceolata L., fig. 779.) is a hardy native with a tuft of long ribbed leaves springing from the crown of the root, long naked flower-stems, and a long moniliform tap-root. It abounds in dry soils, as do several other species of plantain, especially the P. media. On dry soils it affords little herbage, and is often left untouched by cattle. Curtis, Withering, and other British botanists, speak unfavourably of the ribwort as a pasture herb, but Haller attributes the richness of the milk in the Swiss dairies to the flavour of this plant, and that of the Alchemilla, in the mountain pastures. In rich moist or watered lands its herbage is more abundant, and its flavour altered,—a circumstance not uncommon in the vegetable kingdom, but from which it does not always follow that the plant so altered is deserving of culture. In conformity with this observation, though the ribwort is a scanty and rejected herb, on dry soil, it is said by Zappa of Milan to grow spontaneously in every meadow of Lombardy, especially in those which are irrigated. It vegetates early, flowering at the beginning of May, ripens in five weeks, is cut with the Poa trivialis; the height of the leaves is about one foot, and of the stalk a foot and a half; it multiplies itself much by the seed, and a little by the roots, which it continues for some time to reproduce. Ribwort, more especially in a cultivated state, is eaten heartily by every sort of cattle, and in particular by cows, who like it most in May, when it has great influence on the milk, as the hay has on the sheep. In Scotland it is a useful addition to well-acquainted pastures; it is to be pastured by sheep, at the rate of two or three head to the acre. Where kept well fed down by stock, there can be no doubt of its being a very good and nourishing pasture plant for both cattle and sheep; but it is by no means adapted for hay or soilings.

5626. Young says, that he had long before recommended this plant for laying land to grass, and sowed it on his own farm. At the same time, he thinks it extravagant to propose dandelion and sorrel as plants...
proper for a cow pasture, and conjectures that those plants, being found among good ones, have qualities given them which do not properly belong to them; he is likewise inclined to make the same conjecture in respect to narrow-leaved plantain, ribwort, or rib-grass, and should even have preferred danedelion and sorrel. In this he is in the cautious of opposing theory to practice.

5627. Dr. Anderson states, that where close-grazed plantain or rib-grass is well liked by horses and cattle, and yields a very good crop upon rich ground tending to dampness, if it is at the same time soft and spongy; but that upon any soil which has a tendency to bind, or upon dry ground, it furnishes a very second-rate product of Yorks., in the period of the summer, but in the winter, serves well for pasture for cattle and sheep, it is there in high esteem: it is not, however, well eaten by horses. As an article of hay, it is held to be detrimental to the crop; retaining its sap an unusual length of time, and when fully dry falling into a small compass, or being broken into fragments and left behind in the field.

5628. *The culture of the plantain is the same as that of clover; its seed is about the same size, and consequently the same proportion of it will sow an acre.

5629. *The white, furze, or gorse, (Ulex europaeus L., fig. 780), is a well known shrub, found wild on dry light soils, and in rather hilly situations, in the warmer and more temperate parts of Europe; but not frequent nor in Russia, or in Russia, or in the isle of Man, or in Ireland. It has been known as a nourishing food for cattle from a very early period, and has been sown in some parts of England for that purpose and for fuel. Dr. Anderson knows few plants that deserve the attention of farmer more than this hardy shrub, which is easy to multiply, and useful both for the feed of cattle, and the fire of the farmer.

5630. *The culture of the white, is thus given by the same author:—A field of a good dry loamy land, being well prepared, he sowed, along with a crop of barley, the seeds of the white all over the field from fifteen to thirty pounds of seed per acre. Though it is a crop which is not so very valuable, yet it is difficult to grow well; and the farmer, who has prepared his land very well, and has sheltered his crop with a hay cover, may be disappointed in his expectations. It has lately been found excellent food for horses in the Highlands of Scotland. (High. Soc. Trans. vol. v.)

5631. *Another very economical way of rearing whins, but which he has seen practised rather than experienced himself, is this:—Let a farm be enclosed by means of a ditch all round, with a bank thrown up on one side, and if stones can be had, let the face of that bank be lined with the stones, from bottom to near the top, this lining to slope backwards with an angle of about sixty or seventy degrees from the horizon. Let the bank thus lined be covered with dirt, and the grass gathered from the hay mows, and well trampled down, will, upon the top of the bank sow whin-seeds pretty thick, and throw a few of them along the face of the bank. Young plants will appear at once. Let them grow for two years, and then cut them down by means of a hedge-bill, sloping down by the rate of the banks, and let the cuttings be transplanted among the crannies of the stones, the whole face of the bank becomes a close hedge, whose shoots spring up with great luxuriance. If another ditch be made on the other side of the bank, and if this be managed in the same way, and the hedge cut down only once every second year (and in this way it affords two valuable crops of hay and whins), and the alternate years, the fence will at all times continue good, as the hedge at the top will at all times be complete.

This mode of rearing whins is, he remarks, both convenient and economical. But where stones cannot be obtained for making the facing, he has seen sheep-mounds become very solid, and become the mode of covering where stones have prevented him from ascertaining what is the weight of the crop that may be thus attained, but he thinks he may safely venture to say, that it is at least equal to that of a crop of clover and if it be considered, that this allows a good succulent food during winter, on which cattle may be kept as on grass, to him, it will afford a means, he believes, so to supply this want, as to account even a more valuable crop than clover. After being cut, he also remarks, that it springs up the following season with greater vigour than before, and in this situation acquires a degree of health and succulence very different from where it has been observed in possession. He has seen it produce a crop of one season near four feet in length. The pricks too are too soft, and the stems so tender, that very little bruising is necessary; indeed horses, that have been accustomed to this food, would eat it without any bruising at all; but horned cattle, whose masts seem to be more tender, always require it to be well bruised. How long crops of this sort may continue to be annually cut over without wearing out, he cannot say, but he believes a long while in favourable circumstances. One thing, however, it is necessary to attend to in
order to guard against its being destroyed: as, during the beginning of the season, nature seems to be solely employed about the great work of fructification, and it is not till near Midsummer that the whin begins to push forth its wood-branching branches, which achieve great luxuriance during the latter part of the season only, it may happen, that if care be not taken to have the grass that springs up on the field, before the whin begins to send out its shoots, eaten close down, that grass will acquire such a luxuriance before the young branches of the whin begin to advance, as to overtop them, and choke them entirely. Whoever, therefore, has a field under this particular care of the grass planted in it or in the vicinity, or, if the field be in good heart, he will infallibly lose it. The field therefore should be kept as a pasture, bare as possible during the beginning of the season, and the cattle should only be taken from it at such a time as the whin begins to advance with vigour. Under this management, he probably may be kept for many years, and yield full crops; but, unless the mowers be particularly attentive at the beginning, to cut it as low as possible, it will very soon become impossible to cut any of it. It is needful, as the stumps will acquire such a strength as to break the scythe when it happens to touch them.

Secondly. The spurry (Spergula argentea L. fig. 781.) is a diminutive annual weed, on dry sandy corn-lands, in most parts of Europe. In Germany and the Netherlands, it is sown on the corn stubbles, and in the intervals of time that occur between some crops is fed with sheep. It may be seen and raised early in the spring or in autumn or spring. It is said to enrich the milk of cows, so as to make to afford excellent butter; and the moisture fed on it is preferable to that fed on turnips. Hens eat spurry greedily, and it is supposed to make them lay a great number of eggs. Whether in hay, or cut green, or in pasture, Von Thaer observes, it is the most nourishing, in proportion to its bulk, of all forage, and gives the best flavoured milk and butter. It has been recommended to be cultivated in England, but it is not likely that such a plant can ever pay the expense of seed and labour in this country, even on the poorest soil, or at all events, as Prof. Farren observes, we have many better plants for this soil.

5633. The common brome (Bromus erectus, Fr. ; Spartinus erectus, Fr. ; fig. 782.) is cultivated in the southern parts of France, on the poorer sorts of soil, in the same way as a hemp, for the purpose of stripping the bark from it, and converting it into a kind of thread. It is likewise cultivated in these places as a winter food for sheep, and it is said they eat it with great avidity, preferring it to many other plants. It is, however, liable to produce diseases of the urinary passages, by its diuretic qualities. It has been recommended by Young to be cultivated in England as food for sheep and horses, who are said to eat it after they get accustomed to it; also for thatch, ropes, besoms, food for bees, fuel, and burning on the spot to improve the soil. Its culture is the same as that of the whin; but very peculiar, indeed, must be that situation, where its culture is attempted for any of the above purposes. It is a useful protection of game in plantations, from which source abundance may be had for besoms. The Spanish brome (S. junciem L. fig. 783.) might be grown perhaps still more advantageously than the common species.

5634. The parsley (Petroselinum sativum L. ; fig. 784.) is a well known biennial with a large sweet tap-root. It is a native of Sicily, but endures the British winter like a native plant. It is sown along with clover and grass seeds in some places, and especially in Lincolnshire, as a precaution for the rot of the root in sheep, cultivates it largely with success; he sows half a bushel to the acre, with a bushel of rye-grass with spring corn; and he finds that it lasts in the ground till it is permitted to seed. He feeds it constantly; it being excellent for sheep, and, when suffered to get a-head, wonderfully fed upon by pigs in the autumn. After September, it will not, he says, run to seed. When it was ploughed up he obtained good oats. This land was poor, and in the next round of the course, the clover was much the better for the parsley having been sown or the clover omitted; for in a field half parsley, half clover, when the harrow came again to be sown, the parsley was expected. In England, also, it has been sown with success, and greedily eaten by horses, cows, and hogs. The seed requires a longer period to germinate than that of any other agricultural plant, and might probably be advantageously prepared by steaming, and turned on the seedbed. It must be fresh, and two-year-old seed will grow. It is easily procured by the pound or bushel, from the seedsmen, and as easily raised by letting a few drills in a garden plot into ...-ver-stems.

5635. The daisy (Bellis perennis L.) is a well known garden flower, and at the same time a native, and very hardy on dry soils. Like the parsley it is an antiseptic, and has been recommended to be cultivated for the same purposes, and in the same manner.

5. L. 3.
5637. The bird's foot trefoil (Lotifer, Fr.; Lotus corniculatus L., fig. 783) has been tried as a substitute for white clover on moist lands, and seems to succeed very well, but to have no particular advantages over the clover. Lotus major has been found by Mr. Sinclair to afford triple the weight of green food and hay afforded by Lotus corniculatus; its nutritive powers compared with that plant are as nine to eight; but on the whole, he says, both species are greatly inferior to white clover. (Graana. Web. 2d ed. p. 311.) Lotus villus and tetragonalobus, the Lotier cultivé of the French (fig. 786), are a good deal cultivated in France on light soils. The latter is an annual sown in our gardens.

5638. The fens greek (Senecora, Fr.; Trigonolla forínum-graAum L., fig. 787), Greek hay, was formerly cultivated in Italy, and still holds a prominent place in the agriculture of Egypt. In France it is cultivated to a limited extent near Paris for its seeds, which are used in medicine.

5639. The serradilla ( Ornithopus sativus of Persoon's Synopsis) was introduced for purposes of field culture about the year 1818, from Portugal, and sown upon the light barren downs of Thetford in Norfolk, and Aylsham and other places in Bedfordshire. It is said to have produced abundant crops, two feet high, of excellent fodder, where scarcely anything else would grow. Its culture, however, is no longer in use in England, and it does not enter into the agriculture of France.

5640. Galána officinális; Lathyrae cicerá, latifoliá, sylvestris, praténsis, hispéntis, herbáliá, and tingitáni; Eryum villá, and monántheos; Lotus villus, and tetragonalobus, a goá, augusftífolia; Cráceca, Padú-Gráceca, biénis, sápium, and Látea; Anthyllis vulgárea; and Astrágalus glycéphylálos and galéfiorímon, are all used as herbage plants in the agriculture of France.

5641. The oriental banus (Ernias orientális L., fig. 788 a) is a perennial plant, with leaves, branches, and its general habit of herbage, not unlike the wild chicory. It is a native of the Levant, and has been cultivated by way of experiment in the grass garden at Woburn. It is less productive than chicory, bears mowing well, and affords the same nutrition, in proportion to its bulk, as red clover. (Agricultural Chem. p. 574.)

5642. The yarrow (Miltsèneile, Fr.; Achillè Mistlefúlia L., fig. 788 b), the common and alpine ladies mantle (Alchemilla vulgaris and alpina L.), and others, have been tried among perennial grasses, sown in parks, with a view to give favour to milk, butter, motion, and venison. Sinclair considers yarrow as an essential ingredient of the most fattening and healthy pastures. In all the pastures most celebrated for fattening or dairy produce, which he examined in Devonshire, Lincolnshire, and in the vale of Aylesbury, yarrow was present more or less in every part of the surface. (Hort. Gran. Web. 2d edit. p. 412)

Chap. VI.

Cultivated Grasses.

*5643. The forage or hay and pasture grasses, of which we are now about to treat, are found clothing the surface of the earth in every zone, attaining generally a greater height, with less closeness at the root in the warm climates; and producing a low, close, thick, dark green nutritive herbage, in the cooler latitudes. The best grass pastures, those which are most productive and nutritive, are such as are found in countries that have least cold in winter, and no excess of heat in summer. Ireland, Britain, and part of Holland and Denmark, may equal or surpass any countries of the world in this respect; but in every zone where there are high mountains, there are certain positions between the base and summit, where, from the equability of the temperature, turf may be found equal to that in marine islands. It is a singular circumstance with regard to grasses,
that in the greater part of North America, the sorts that grow naturally on the plains are almost all annuals, and consequently with the first frost they die, and the ground remains naked till a fresh crop rises from the self-sown seeds next spring. Nearly the same thing may be said of Poland and Russia, with the exception of the banks of rivers and the mountains.

5644. The universal presence of the forage grasses, and the rapidity with which all soils become covered with them when left uncultivated, are the obvious reasons why their systematic selection and culture are of but recent date. Though the Romans cultivated clovers, and were careful of their meadows, it does not appear that the seeds of the proper grasses were collected and sown by them. None of the agricultural writers, from Peter of Bologna to Parkinson in 1641, say a word about sowing grasses, though they all mention clover and lucerne. This branch of culture appears to have originated in England about the middle of the seventeenth century, and the grass made choice of was the ryegrass. The first mention of it for cultivation is in Dr. Plot's *Oxfordshire*, printed in 1677. "They have lately sown," says he, "ryegrass, or the Grimen fillicium, by which they improve any cold, sour, clay-weeping ground, for which it is best, but good also for drier upland grounds, especially light stony or sandy land, which is unfit for sainfoin. It was first sown in the Chiltern parts of Oxfordshire, and since brought hither Oxbridge by one Eyres, an ingenious husbandman of Islep, who, though at first laughed at, has since been followed even by those very persons that scorned his experiment." The first grass tried after ryegrass appears to have been the *Phleum pratense*, by Rocque of Walham Green, about 1700. Soon afterwards the seed of cock's-foot grass was introduced from Virginia, under the name of orchard-grass, by the Society of Arts. (Ann. Reg. 1763. 141.); fox-tail was tried at a later period, on the suggestions of Stillingfleet and Curtis.

5645. *Stillingfleet*, about 1728, drew the attention of the reading agriculturist to the selection of different species of grasses; as did Dr. Anderson about the same time, and Swayne (*Aridum Pasta*) and Curtis (*Observations on British Grasses*) soon afterwards. The origin of this attention to grasses and native plants may be traced to the practice of forming local floras by botanists, and especially to the *Flora Svecica* of Linnaeus; and the *British Flora of Hudson, Withering, Lightfoot, Smith*, &c. in which the grasses and economical properties of the plants were mentioned; and, in imitation of Linnaeus, particular notice taken of the animals which fed upon them.

5646. John Duke of Bedford made the latest and most laborious efforts towards attaining a knowledge of the comprehensive value of all the British and some foreign grasses for cultivation. The result is given in an appendix to Sir H. Davy's *Agricultural Chemistry*, and more at large in Sinclair's *Hortus Graminicis*, Svo. 2d edit. 1825, a work which may truly be said to form an epoch in this department of agriculture, and which will probably long continue to be the ground-work of all that shall continue to be done in this branch of the subject.

*5647. With respect to the general culture of grasses, though no department of agriculture is more simple in the execution, yet, from their nature, considerable judgment is required in the design. Though grasses abound in every soil and situation, yet, all the species do not abound in every soil and situation indifferently. On the contrary, no class of perfect plants is so absolute and unalterable in its choice in this respect. The creeping-rooted and stoloniferous grasses will grow readily on most soils; but the fibrous-rooted species, and especially the more delicate upland grasses, require particular attention as to the soil in which they are sown; for in many soils they will either not come up at all, or die away in a few years, and give way to the grasses which would naturally spring up in such a soil when left to a state of nature. Hence, in sowing down lands for permanent pasture, it is a good method to make choice of those grasses which thrive best in adjoining and similarly-circumstanced pastures for a part of the seed; and to mix with these what are considered the very best kinds.

5648. The most important feature in the culture of pasture grasses is mixture of sorts. The husbandman, observing one of the most scientific agriculturists in Scotland, who clothes his fields only with ryegrass and clover, employs a limited machinery, the farmer being unproductive in summer, the hatter moderately so in spring; but when he, for this purpose, uses a variety of plants differing in their habits of growth, and periods of luxuriance, a numerous and powerful machinery is kept successively in full operation. (Dear. Journ. Agric. vol. ii. p. 564.)

5649. The effect of a mixture of grasses may be accounted for from some species putting forth their foliage, and reaching a maximum of produce at different periods from other kinds. From some being gregarious or social, and others solitary and never producing a close turf; by sowing seeds of several species together, which are dissimilar in their habits of growth, and arrive at a maximum of produce at different periods of summer and autumn, there is secured throughout the season a succession of fresh herbage, rendered, by the erect and creeping foliage of the different species, so dense and abundant as greatly to surpass in quantity that obtained from the cultivation of two or three kinds only. (Ibid. p. 246.)

5650. New and excellent varieties of many of the grasses, especially those used or fit to be used in the convertible husbandry, might no doubt be obtained by selection and cross-breeding, and it is much to be wished that this were attempted by cultivators.

5651. The grasses to be here treated of may be classed as tall sorts, or those best fitted for hay; and dwarf grasses, or those fit only for pasturage: those experimented on at Welburn will next be noticed.

**Sec. I. Tall or Hay Grasses of temporary Duration.**

5652. The hay grasses for the purposes of agriculture may be advantageously divided into those of temporary, and those of permanent duration.

**Subsect. I. Tall or Hay Grasses of temporary Duration.**

5653. The most valuable of this division are the biennial, or, as it is commonly but erroneously called, the annual, perennial, and subperennial *ryegrass* (fig. 769. a), the
cock's-foot grass, and wooly soft grass (c). Where a crop of hay is desired within the year, it is necessary to resort to such grasses as are annuals in the strict sense of the word; and none can be better for this purpose than the common oat (Avena sativa), cut and made into hay when it comes into flower. Next in order may be mentioned the other cereal grasses and the annual varieties of Brönum: the latter, however, are very coarse grasses, though prolific in culm.

5654. The biennial rye-grass (Lolium perenne var. biéne L.) is well known, as being universally sown, either with or without clover, among corn crops, with a view to one crop of hay in the succeeding season.

It attains a greater height, and produces a longer broader spike of flowers, than the perennial rye-grass, and the produce in hay is considered greater than that of any other annual grass, equally palatable to cattle. It prefers a rich loamy soil, but will grow on any surface whatever, not rock or undecayed bog.

5655. The perennial rye-grass (Lolium perenne L. Terre vivace, Fr.; Daurende Latche, Ger.; and Loglio vivace, Ital.) differs from the other in being of somewhat smaller growth, and in abiding for several years, according to the variety and the soil and culture.

5656. Many consider this grass coarse, benty, and very exhausting to the soil; but, after all the experiments that have been made on the other grasses, none have been found to equal it for a course of mowing and pasturing for two, three, or seven years. It is sown in Italy, and especially in Lombardy, and also in France and Germany, along with clover, for the same purpose. In this country it is mostly used with spelt and barley, and others described with spelt and wheat. It is remarked, though some have tried other species, both in these countries and in England, they have in the end returned to rye-grass. When intended as a pasture-grass, it is sown in the field generally, or in black soil fields, but it is also sown with cumb in the spring. When sown in the field it is usually kept free of other weeds, and the hay is good, though containing more rye-grass than when sown with a mixture of other grasses. It is remarkable, however, that the rye-grass is not so much injured by passage of reapers as is the grass sown with a mixture of other grasses. Sometimes, when sown in the field, it may be taken and kept for some time to come without it being a favourite grass among farmers. But the latter is not considerable, the plant improves higher the more it is used; and it will probably soon be the favourite grass among farmers.

5657. The seed of perennial rye-grass is not to be distinguished from that of the annual variety. It may be collected by hand, in most parts of Britain, from old pastures, and a considerable quantity is annually so procured in Kent and Sussex. It is also grown purposely for seed in England and Scotland. Formerly it was the practice for farmers to collect the seed which dropped from the hay used by their horses; but rye-grass, grown for hay, is now cut, by all industrious farmers, before it is in the perfect state, in order to collect the glumes or empty husks. It has also been a common practice, in regard to rye-grass, to let the mixed crop of that and clover stand till the seeds of the former have attained a considerable degree of ripeness, when it is cut down and made into hay, in the usual manner; and the seeds of the rye-grass are separated by the use of the flail, commonly before the hay is put into the field ricks. Sometimes, when but a small quantity is wanted, the hay is merely shaken well upon a cloth, when it is building in the stack-yard; or afterwards in the stable-loft, before it is put into the horse's racks. But in all these methods, in order to obtain good seed, the clover must remain uncut beyond the proper season; and it is thus materially injured in quality, while the value of the rye-grass seed, in such a crop, is merely a secondary consideration.

5659. When seed is the principal object of the culture of rye-grass, it ought not to be mixed with clover at all, though it may be sown along with any of the kinds of corn, and treated the year after in every respect as a crop of corn; bound up in sheaves, built in stacks, threshed with the flail, and dressed by the winnowing-machine in the same manner.

5660. The difficulty of distinguishing between the annual and perennial varieties of rye-grass has led to the practice, in some places, of cutting or pasturing the first year's crop, and taking a crop for seed the second year. If the growth of the rye-grass plants be close and vigorous the second year, there is reason to be satisfied that the seed is of the perennial variety; and though red clover was sown with the rye-grass, a great part of it disappears by that time, and forms but a small portion of the second year's cutting. (Sup. Encyc. Brit. art. Agr.)
5661. The cock's-foot grass (Dactylis glomerata L., fig. 788. b) is an imperfect perennial, and grows naturally on dry sandy soils. This grass may be known by its coarse appearance, both of the leaf and spike, and also by its whitish green hue.

5662. One writer says, he has cultivated it largely, and to his satisfaction, on wet loams on a clay marl bottom, upon which the finer grasses are apt to grow in way in a few years to the indigenous produce. If suffered to rise high, it is very coarse; but, led close, is a very valuable sheep pasture. He has sown two bushels an acre, and fills, common red clover; and when the grass is cut out, it often abides well in it. It grows well in winter. It has been found highly useful as an early sheep feed. It is early, Hardy, and productive, but is a coarser plant than ryegrass, and requires even greater attention in regard to being cut soon, or fed close. It does best by itself, and the time of its ripening being different from that of clover, it does not suit well to be mixed with that plant. The pasturage it affords is luxuriant, and particularly agreeable to sheep. It is cultivated to a great extent, and with astonishing success, at Holkham. The quantity of sheep kept upon it, summer and winter, is quite surprising; and the land becomes rent-crowned by being thus grassed, and enriched by the manure derived from the sheep. A field, in the park at Woburn, was laid down in two equal parts, one part with ryegrass and white clover, and the other part with cock's-foot and red clover; from the spring till midsummer, the sheep were allowed to rest on it; but after that time they left it, and other grasses filled the space. The writer states, it is stated, that Sinclair of Woburn considers no grass so well suited for all purposes as cock's-foot; and in the second edition of the Hortus Gramineus Woburnensis, it is observed, that if one species only is thought preferable to another in the alternate husbandry, that species is the Dactylis glomerata, from its more numerous merits. But a certain supply of the most nutritious herbage throughout the season will be in vain looked for from any one species of grass, and can only be found where nature has provided it in a combination of many. None appear better fitted for mixing with Dactylis than Festuca duriâscula and pratensis, Poa trivialis, Holcus avenaceus, Phleum pratense, Lolium perenne, and white clover. "A combination thus formed, of three parts cock's-foot, and one part of these species in 1:1:1 mixture, will secure the most productive and nutritive pasture in alternation with grain crops, on small areas of the best land, and even on poor, inferior soils, under the circumstances of unfavorable seasons, will afford nutritive herbage, when otherwise the land would have been comparatively devoid of it, if one species of grass only had been employed." (Hort. Gram. Web. 2d ed. 414.)

5664. The woolly soft grass (Holcus lanatus L., fig. 580. c) is an imperfect perennial, and rather late flowering grass, of a short unobtrusive appearance, and found chiefly in poor dry soils. It is, however, a very common grass, and grows on all soils, from the richest to the poorest. It affords abundance of seed, which is light, and easily dispersed by the wind.

5665. It was cultivated at Woburn on a strong clayey loam, and the proportional value which the grass at the time the seed is ripe, bears to the grass at the time of flowering, is as 5 to 7 nearly. The proportion value which the grass of the lattermarch bears to the grass at the time of flowering, is as 6 to 10; and to the grass at the time the seed is ripe, as 6 to 14. Sixty-four of each, being mixed with the ryegrass, as well as the clover and the grasses of the preceding paragraph, and the straws simply, are therefore of equal proportional value; a circumstance which will point out this grass to be more valuable for permanent pasture than for hay. The above details prove, that a loss of nearly one third of the value of the crop is sustained, if left to the period when the seed is ripe, though the proportion of the grass at the time of flowering is greater, the proportion of the grass is less growing after the period of flowering, but uniformly decreases; and the loss of lattermarch (from the rapid growth of the foliage after the grass is cropped) is very considerable. These circumstances point out the necessity of keeping this grass closely cropped, either with the seytle or catttle, to reap the full benefit of its merits.

5666. According to Sinclair, of Woburn, "it appears to be generally disliked by all sorts of cattle. The produce is not so great as a view of it in the fields would indicate; but being left almost entirely untouched by cattle, it appears the most productive part of the herbage. The hay which is made of it, from the number of downy hairs which cover the surface of the leaves, is soft and spongy, and disliked by cattle in general." The Woburn experiments lead to the conclusion that the Holcus mollis is a better hay plant than the species here noticed; but as that is a more durable perennial it is less fitted for the temporary purposes of this section.

5667. The culture of these grasses may be considered the same as that of ryegrass, which was discussed when treating of clover and rye-grass. (5540.) The seeds of all of them are sold by the principal seedsmen, or may be gathered on grass-fields, or hedge wastes, by women or children at an easy rate.

Subsect. 2. Tall or Hay Grasses of permanent Duration.

5668. No permanent grass has been found equal to the ryegrass for the purposes of convertible husbandry, but others have been selected which are considered superior for hay meadows. The principal of these are the fescue, fox-tail, and meadow-grass. Agriculturists, indeed, are not all agreed on the comparative merits of these grasses with rye-grass; but there are none who do not consider it advisable to introduce a portion of each, or most of these species along with ryegrass, in laying down lands to permanent pasture. The nutritive products of these grasses, of perennial rye-grass, and of that singular grass florin, are thus given by Sir H. Davy: —
### Systematic Name | English Name | Whole weight | Marture of soluble or nutritive matter | Sugar or starch | Gluten or albumen | Extract of matter rendered lose during evaporation
--- | --- | --- | --- | --- | --- | ---
*Festuca hololea* (fig. 790. c) | Spiked fescue grass | 19 | 15 | 2 | — | 2
*Holcus odoratus* | Sweet-scented soft grass | 82 | 72 | 4 | — | 6
*Anthoxanthum vernum* | Sweet-scented vernal grass | 50 | 43 | 4 | — | 3
*Alopecurus pratensis* (d) | Meadow fox tail grass | 32 | 23 | 3 | — | 6
*PoA fettulis* (e) | Meadow grass | 78 | 65 | 6 | — | 7
Trivialis (f) | Rough meadow grass | 30 | 29 | 5 | 1 | 2
*Cynosurus cretulus* (g) | Rested dog's-tail grass | 35 | 28 | 4 | 1 | 5
*Lolium perenne* | Perennial ryegrass | 39 | 26 | 5 | 1 | 2
*Agrostis stolonifera* | Fiorin | 54 | 46 | 5 | 1 | 3
*Agrostis stolonifera* | Fiorin cut in winter | 70 | 64 | 8 | 1 | 3

5669. Of the *fescue* grass there are three species in the highest estimation as meadow hay grasses, viz. the meadow, tall, and spiked fescue. (fig. 790. a, b, c.)

5670. The *F. pratensis* (c), or the meadow or fertile fescue grass, is found in most rich meadows and pastures in England, and is highly grateful to every description of stock. It is more in demand for laying down meadows than any other species except the rye-grass. By the Woburn experiments, the value of this grass at the time the seed is ripe, is that of the grass at the time of flowering, as 6 to 18. The loss which is sustained by leaving the crop of this grass till the seed be ripe is very great. That it loses more of its weight in drying at this stage of growth, than at the time of flowering, perfectly agrees with the deficiency of nutritive matter in the seed crop, in proportion to that in the flowering crop: the straw being succulent in the former, they constitute the greatest part of the weight; but in the latter they are comparatively withered and dry, consequently the leaves constitute the greatest part of the weight.

5671. The tall or inscrifler fescue grass (Festuca eliktor E. B. d) is closely allied to the *Festuca pratensis*, from which it differs in little, except that it is larger in every respect. The produce is nearly three times that of the *F. pratensis*, and the nutritive powers of the grass are superior, in direct proportion, as 6 to 8. The proportional value which the grass at the time the seed is ripe, bears to the grass at the time of flowering, is as 12 to 29. The proportional value which the grass of the latter piece bears to that of the crop, is as 16 to 26; and to the grass at the time the seed is ripe, as 16 to 16 inverse. Curtis observes, that as the seeds of this plant, when cultivated, are not fertile, it can only be introduced by parting its roots and planting them out; in this there would, says he, be no great difficulty, provided it were likely to answer the expense, which he is strongly of opinion it would in certain cases; indeed he has often thought that meadows would be best formed by planting out the roots of grasses, and other plants, in a regular manner; and that, however singular such a practice may appear at present, it will probably be adopted at some future period; this great advantage would, he says, attend it, noxious weeds might be more easily kept down, until the grasses and other plants had established themselves in the soil.

5672. The spiked fescue grass, or darnel fescue grass (Festuca hololea L. e), resembles the rye-grass in appearance, and the tall fescue grass in the inferiority of its seeds. It is considered superior to rye-grass either for hay or permanent pasture, and improves in proportion to its age, which is the reverse of what takes place with the rye-grass.

5673. The meadow foxtail grass (Alopecurus pratensis, d) is found in most meadows; and when the soil is neither very moist nor very dry, but in good heart, it is very productive. It also does well on water meadows. Sheep and horses seem to have a greater relish than oxen for this grass.

5674. In the Woburn experiments, it was tried both on a sandy loam and a clayey loam, and the result gave nearly three fourths of produce greater from a clayey loam than from a sandy soil, and the grass from the latter is comparatively of less value, in proportion as 4 to 6. The straw produced by the sandy soil are deficient in number, and in every respect less than those from the clayey loam; which will account for the unequal quantities of the nutritive matter afforded by them; but the proportional value in which the grass of the latter exceeds that of the crop at the time of flowering, is as 4 to 5; a difference which appears extraordinary, when the quantity of flower-stalks which are in the grass at the time of flowering is considered. In the *Anthoxanthum odoratm* the proportional difference between the grass of these crops is still greater, nearly as 4 to 9; in the *PoA pratensis* they are equal; but in all the
latter flowering grasses experimented upon, the flowering straws of which resemble those of the *Alopecurus pratensis*, or *Anthoxanthum odoratum*, the greater proportional value is always, on the contrary, found in the grass of the flowering crop. Whatever the cause may be, it is evident that the loss sustained by taking the crops of these grasses at the time of flowering is considerable. The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe, as is 6 to 9. The proportional value which the whole of the lattermath crop bears to that at the time the seed is ripe, is as 5 to 9; and to that at the time of flowering, proportionably as 12 to 24. Next to the grasses, this is the greatest reputation for laying down mowing grounds; but it is unfortunately subject to the rust in some situations.

5675. Of the meadow grass there are two species in esteem as hay plants, the smooth-stalked, and roughish. These plants compose the greater part of the celebrated Orcheston meadows near Salisbury, and also of the meadows near Edinburgh.

5676. The great or smooth stalked meadow grass, the spear grass of America (*Pica pratensis*, e), is distinguished by its height, smooth stem, and creeping roots. According to Sole it is the best of all the grasses: its foliage begins to shoot and put on a fine verdure early in the spring, but not so soon as other grasses. Every animal that eats grass is fond of it; while it makes the best hay, and affords the richest pasture. It abounds in the best meadows about Laycock and Chippenham, and has the valuable property of abiding in the same land, while most other grasses are continually changing. According to some it delights in rather a dry than a moist soil and situation, on which account it keeps its verdure better than most others in dry seasons; but it thrives most luxuriantly in rich meadows.

5677. By the Woburn experiments, the proportional value in which the grass of the lattermath exceeds that of the flowering crop, as is 6 to 7. The grass of the seed-crop, and that of the lattermath, are of equal value. This grass is, therefore, of least value at the time the seed is ripe; a loss of more than one fourth of the value of the whole crop is sustained if it is not cut till that period; the straws are then dry, and the root-leaves in a sickly decaying state: those of the lattermath, on the contrary, are luxuriant and healthy. This species sends forth flower-stalks but once in a season, and those being the most valuable part of the plant for the purpose of hay, it will, from this circumstance, and the superior value of the grass of the lattermath, compared to that of the seed-crop, appear well adapted for permanent pasture. It was of this grass that the American prize bonnet, in imitation of Leghorn, was manufactured by Miss Woodhouse.

5678. The roughish meadow grass (*Pica trivialis* L., f) delights in moist, rich, and sheltered situations, when it grows two feet high, and is very productive. By the Woburn experiments it appears that the proportional value in which the grass of the seed-crop exceeds that at the time of flowering, is as 8 to 11. The proportional value by which the grass of the lattermath exceeds that of the flowering grass is as 9 to 12; and that of the seed-crop, as 11 to 12. Here, then, is a satisfactory proof of the superior value of the crop at the time the seed is ripe, and of the consequent loss sustained by taking it when in flower; the produce of each crop being nearly equal. The deficiency of hay in the flowering crop, in proportion to that of the seed-crop, is very striking. Its superior produce, the highly nutritive powers which the grass seems to possess, and the season in which it arrives at perfection, are merits which distinguish it as one of the most valuable of those grasses which affect moist rich soils and sheltered situations: but on dry exposed situations, it is altogether incomconsiderable; it yearly diminishes, and ultimately dies off, not unfrequently in the space of four or five years.

5679. The above are six of the best British grasses, for either dry or watered meadows. The seeds of the meadow fescene, fox-tail, and smooth and rough meadow grasses may be had from the seedmen, and they are sown in various proportions with the clovers and rye-grass. The seeds of the two sorts of meadow grass are apt to stick together, and require to be well mixed with the others before being sown. The tall and spiked fescue grasses, having a number of barren flowers, are not prolific in seeds, and they are therefore seldom to be got at the seed-shops; though they may occasionally be had there gathered from plants in a wild state.

5680. As hay grasses, adapted for particular soils and situations, the cat's tail or Timothy, floating fescene, and fiorin grass, have been recommended; but it cannot be said that the opinions of cultivators are unanimous in their favour. Timothy has certainly been found to answer well on moist, peaty soils, and in several cases florin also.

5681. The cat's tail or Timothy grass (*Phleum pratense* L., fig. 791. a) is a native plant, and found both in dry and moist soils. It was first brought into notice by Timothy Hudson, about 1780, who introduced it from Carolina, where it was in great repute. On moist rich soils it is a prolific grass, but late; on dry soils it is good for little, and for cultivation in any way is disapproved of by Withering, Swaine, Curtis, and others, as having no properties in which it is not greatly surpassed by the *Alopecurus pratensis*.

5682. The Woburn experiments, however, present this grass as one of the most prolific for hay. Sixty-four drachms of the straws afforded seven drachms of nutritive matter. The nutritive powers of the
straws simply, therefore, exceed those of the leaves, in the proportion of 28 to 8; the nutritive powers of the grass, at the time of flowering, exceeded those of the grass at the time the seed is ripe, in the proportion of 8 to 10. The comparative merits of this grass will, from the above particulars, appear to be very great; to which may be added the abundance of fine foliage that it produces early in the spring. In short, it is inferior to Poa annual. Commonly, of the soil in which the seed is ripe, exceeds that of the grass at the time of flowering, in the proportion of 28 to 16, a circumstance which raises it above many others; for from this property its valuable early foliage may be devoted to an advanced period of the season, without injury to the crop of hay, treatment which in grasses that send forth their flowering straws too early in the season would cause a loss of hay, and half the value of the crop, as clearly proved by former examples; and this property of the straws makes the plant peculiarly desirable for hay. In moist and peaty soils it has in various instances been found highly productive.

5683. The floating fescue grass, Festuca fluitans (L.) is found in rich swamps, especially in Cambridgeshire, where it is said to produce the peculiar flavour to Cottenham and Cheddar cheese. It is also found in ditches and ponds in most parts of the country.

5684. It is greedily devoured by every description of stock, not excepting hogs and ducks, and eagerly devours the seeds, which are small, but very sweet and nourishing. They are collected in several parts of Germany and Poland, under the name of manna-seeds (schwaden), and are esteemed a delicacy in those countries. It is also a tenacious weed, and in moist soil is given to horses that have the worms; but they must be kept from water for some hours afterwards. Geese, and other water-fowl, are very fond of the seeds. So also are fish; trout, in particular, thrive in those rivers where this grass grows in plenty. It has been recommended to be sowed on meadows that admit flooding; but Curtis justly remarks, that the flote-fescue will not flourish except in land that is constantly under water, or converted into a bog or swamp.

5685. The water meadow grass (Poa aquatica, L.) is found chiefly in marshes, but will grow on strong clays, and yield, as the Woburn experiments prove, a prodigious produce, flowering from June to September. It is one of the largest of our grasses.

5686. In the fen of Cambridgeshire, Lincolnshire, &c., immense tracts, that used to be overflowed and to produce useless aquatic plants, and which, though drained by mills, still retain much moisture, are covered with this grass, which not only affords rich pasturage in summer, but forms the chief part of the winter fodder. It has a powerfully creeping root; and grows so fast, and is so productive, that it is cut off three in one season near the Thames. It grows not only in very moist ground, but in the water itself; and with cut-tail, burr-reed, &c., soon fills up ditches, and occasions them to require frequent cleansing. In the fen, this is a formidable plant, even in slow rivers, and sometimes the instrument called a bear, which is an iron roller, with a number of pieces of iron, like small spades, fixed to it; this is drawn up and down by the river by horses walking along the bank, and tears up the plants by the roots, and is carried down the stream by the current. The grass was, however, cultivated at Woburn on a strong tenacious clay, and yielded considerable produce.

5687. The firion grass (Agrrostis stolonifer, L.) is a very common grass both in wet and dry, rich and poor situations. Few plants appear to be more under the influence of local circumstances than this grass. On dry soils it is worth nothing; but on rich marl soils, and in a moist soil, if we may put confidence in the accounts given of its produce in Ireland, it is the most valuable of all herbage plants.

5688. It was first brought into notice by Dr. Richardson in 1809, and subsequently extolled, and its culture detailed in various pamphlets by the same gentleman. It appears to be exclusively adapted for moist peat soils or bogs. In The Code of Agriculture it is said, "On mere bogs, the firion yields a great weight of herbage, and is, perhaps, the most useful plant that logs can produce. According to Sir H. Davy, the firion grass, to the turf of which a name is given, is a most valuable plant, and is marvelously useful in cold clays unfitted for other grasses. In light sands, and in dry situations, its produce is much inferior as to quantity and quality. He saw four square yards of firion grass cut in the end of January, in a meadow experiment, to the cultivation of horsetail and grass is 850 square feet; 20 square yards of firion was found to produce 700 pounds of hay. It is also of use in meadow seed, and thrives in all sorts of open meadows, growing almost at the surface. It thrives in the open field, and in all sorts of meadows, as well as in marshy ground. It is also grown as an ornament in beds and borders, and is cut for hay. It is a valuable plant for hay, as it yields a great quantity of hay, and is esteemed a valuable addition to the hay, and is, perhaps, the most useful plant that logs can produce."

5689. There are other species of Agrrostis, as the A. palustris and rhenensis, and some varieties of the A. stolonifer, that on common soils are little different in their appearance and properties from firion. On one occasion a narrow-leaved creeping-bent (A. stolonifer, L.) has been grown in the account of the Woburn experiments. "From a careful examination of the creeping-bent with narrow leaves, it will undoubtedly appear to possess merit as worthy of attention, though perhaps not so much as the former. It requires the same care as the natural plants, which have been so carefully and judiciously cultivated at Woburn."

5690. The culture of firion is different from that of other grasses. Though the plant will ripen its seeds on a dry soil, and these seeds being very small, a few pounds would be sufficient for an acre, yet it is generally propagated by stolones or root-shoots. The ground being well pulverised, freed from weeds, and laid inch deep, the soil is well tamped, and the seed is broadcast. Such an advantage is not afforded, nor are the seed of a few inches asunder, to be drawn along its surface, with a hand or horsehoe, or on soft lands with the hoe-rame. In the bottom of these drills, the firion shoots (whether long or short is of no consequence) are set, so that their ends may touch each other, and the surface rolled to render it fit for the sowing. In six months the whole surface will be covered with the verdure, and if the planting be performed early in spring, a large crop may be had in the following autumn. Any season will answer for planting, but one likely to be followed by showers and heat is to be preferred. They who have not the means to cultivate this grass will consult Dr. Richardson's Essay on Fescue Grass, and also The Farmer's Magazine for 1810-14. Our opinion is, that neither firion, Timothy, or floating fescue, is ever likely to be cultivated in Britain; though the latter two may perhaps succeed well on the stony and moist rich soils of Ireland, where, to second the influence of the soil, there is a moist warm climate.
5691. A number of other species of tall grasses, well adapted for meadows and hay-making, might be here enumerated; but we have deemed it better to treat only of the most popular sorts, of which seeds may be purchased; all the others of any consequence will be found in a tabular view (Sect. 111.), accompanied by a summary statement of their products in hay and aftermath, nutritious matter, and general character.

5692. The preparation of the soil, and the sowing of the usual meadow grasses, differ in nothing from those of clover and ryegrass already given. The after-treatment of dry meadows, including the making of natural hay, will be found in the succeeding Chapter on the management of grass-lands; that of watered meadows was naturally given when treating of their formation. (4451.)

Sect. II. Grasses chiefly adopted for Pasturage.

5693. In treating of pasturage grasses we shall make a selection of such as have been tried to some extent, and of which the seeds are in the course of commerce. On soils in good condition, and naturally well constituted, no better grasses can be sown for pasturage than those we have described as tall grasses for hay-meadows; but for early and late pasturage, and secondary soils, there are others much more suitable.

5694. The pasture grasses for early pasturage on all soils are the Anthoxanthum odoratum, Holcus odoratus, *Avena* pubescens, and *Poa* annua.

5695. The pasture grasses for late herbage on all soils are chiefly the different species of Agristis and Phleum.

5696. The pasture grasses for poor or secondary soils are the Cynosurus cristatus, Festuca duriscula and ovina, *Poa* compressa, cristata, and angustifolia.

5697. The grasses that afford most nutritious matter in early spring, are the fox-tail grass and the vernal grass; the former has been already mentioned as one of the best hay-grasses.

5698. The sweet-scented vernal grass (*Anthoxanthum odoratum*, fig. 792. a) is common in almost all pastures, and is that which gives the fragrance to natural or meadow-hay. It is chiefly valuable as an early grass; for, though it is eaten by stock, it does not appear to be much relished by them. From the Woburn experiments, it appears that the smallness of the produce of this grass renders it improper for the purpose of hay; but its early growth, and the superior quantity of nutritious matter which the aftermath affords, compared with the quantity afforded by the grass at the time of flowering, cause it to rank high as a pasture-grass, on such soils as are well fitted for its growth; such are peat-bogs, and lands that are deep and moist.

5699. The downy oat grass (*Avena* pubescens, b), according to the Woburn experiments, possesses several good qualities, which recommend it to particular notice; it is hardy, early, and more productive than many others which affect similar soils and situations. Its growth after being cropped is tolerably rapid, although it does not attain to a great length if left growing; like the *Poa* pratensis it sends forth flower-stalks but once in a season, and it appears well calculated for permanent pasture on rich light soils.

5700. The annual meadow grass (*Poa* annua, c) is the most common of all grasses, and the least absolute in its habits. It is almost the only grass that will grow in towns and near works where the smoke of coal abounds. Though an annual grass, it is found in most meadows and pastures perpetually flowering, and affording an early sweet herbage, relished by all stock, and of as great importance to birds as wheat is to man. It hardly requires to be sown, as it springs up every where of itself. However, it may not be amiss to sow a few pounds of it per acre wherever perpetual pasture (not hay) is the object.

5701. The fine bent grass (*Agristis vulgaris*, d) is one of the most common grasses, and, according to the Woburn experiments, one of the earliest. The *A. pallescens* is nearly as early in producing its foliage, though both flower later, and neither is very prolific either in bulk or nutritious matter.

5702. The narrow-leaved meadow grass (*Poa* angustifolia, e), though it flowers later, yet is remarkable for the early growth of the leaves. According to the Woburn experiments the leaves attain to the length of more than twelve inches before the middle of April, and are soft and succulent; in May, however, when the flower-stalks make their appearance, it is subject to the disease termed rust, which affects the whole plant; the consequence of which is manifest in the great deficiency of produce in the crop at the time the seed is ripe, being then one half less than at the time of the flowering of the grass. Though this disease begins in the straws, the leaves suffer most from its effects, being at the time the seed is ripe completely dried up; the straws, therefore, constitute the principal part of the crop for mowing, and they contain more nutritious matter, in proportion, than the leaves. This grass is evidently most valuable for permanent pasture, for which, in consequence of its superior, rapid, and early growth, and the disease beginning at the straws, nature seems to have designed it. The grasses which approach nearest to this in respect of early produce of leaves, are the *Poa* furtii, *Dactylis* glomerata, *Phleum pratense*, *Alopecurus pratensis*, *Avena* elatior, and *Eri* mus littlcrew, all grasses of a coarser kind.
5703. The best natural pastures of England, examined carefully during various periods of the season, were found by Sinclair of Woburn to consist of the following plants: —

- Alopecurus pratensis
- Holcus lanatus
- Phleum pratense
- Festuca pratensis
- Poa annua
- Avena pratensis
- Bromus arvensis (frequent)

These afford the principal grass in the spring, and also a great part of the summer produce: —

- Festuca rubra
- Poa pratensis
- Trifolium pratense
- Trifolium repens

These yield produce principally in summer and autumn: —

- Agrostis stolonifera and palustris
- Trifolium repens

These vegetate with most vigour in autumn: —

- Ranunculus aquatilis
- Plantago lanceolata

The first and last of these plants are to be considered injurious; and the other is of little value as herbage. (Hort. Gram. Web. ed edit. 133.)

5704. The above mixture sown at the rate of four or five bushels to the acre, on well prepared soil without corn or other crop of any kind, could hardly fail of producing excellent pasture in the following year, and for an indefinite period. The best time for sowing is July or August, as spring-sown seeds are apt to suffer with the droughts of June and July. Fifteen of the above sorts are to be had from the seed-shops; and all of them may be gathered from natural pastures, or bespoken from collectors. Sinclair of Woburn, having entered into the seed and nursery business, and having expressed his intention to devote his particular attention to supplying the public with grass and other agricultural seeds, will probably render such seeds more common in commerce. (Adel. by Cormack, Son, and Sinclair.)

5705. Of late pasture grasses the different species of eat’s-tail (Phleum) and bent-grass (Agrostis) are the chief, and especially the Timothy and florin grass. The grasses, Sir H. Davy observes, that propagate themselves by stolones, the different species of Agrostis, supply pasture throughout the year; and the concrete sap, stored up in their joints, renders them a good food even in winter.

5706. Of pasture grasses for inferior soils one of the most durable is the dog’s-tail grass (Cynosurus cristatus, fig. 793. a). This is a very common grass on dry, clayey, or firm surfaces. It is one of the best grasses for parks, being highly relished by the South Down sheep and deer.

5707. The hard fescue grass (Festuca duriuscula, b) is one of the best of the dwarf sorts of grasses. It is grateful to all kinds of cattle; hares are very fond of it; at Woburn they crop it close to the roots, and neglect the Festuca ovina and Festuca rubra, which grow contiguous to it. It is present in most good meadows and pastures; and, with F. ovina, is the best for lawns.

5708. The Festuca globosa (c), and hordetformis (d), greatly resemble the hard fescue, and may be considered equally desirable as pasture and lawn grasses.

5709. The yellow oat grass (Avena flavescens) is very generally cultivated, and appears, from the Woburn experiments, to be a very valuable grass for pasture on a clayey soil.

5710. Of pasture grasses for inferior soils and upland situations, one of the principal is the Festuca ovina, or sheep’s fescue grass (fig. 794. a). This grass is peculiarly adapted for hilly sheep pastures. It is a low hard grass, but relished by all kinds of cattle. According to Sinclair’s experience, “on dry soils that are incapable of producing the larger sorts, this should form the principal crop, or rather the whole; for it is seldom or never, in its natural state, found intimately mixed with others, but by itself.”

5711. The Poa alpina (b), Alopecurus alpinus, and Aria carpi- tica (c), Briza media (d), and minima, and Agrostis hamiis and vulgaris, are all dwarf mountain grasses, well adapted for hilly parks or lawns.
5712. On the culture of these grasses it is unnecessary to enlarge, as it must obviously be the same as that of ryegrass or any of the others.

5713. The chief difficulty is to get the seed in sufficient quantity, for which a good mode is to contract with a seedman, perhaps a year beforehand, for the quantity wanted. With all the pasture grasses, except the last class, we should recommend at least half the seed to be of that of the perennial ryegrass; and we think it should also form a considerable part of the seeds used in laying down all meadows, except those for the aquatic or marshy purposes. These, if possible, are best destroyed by fire, and therefore neither ryegrass, nor any other grass, should ever be sown with Timothy grass or florin.

5714. The formation of grassy surfaces by distributing pieces of turf over them has long been practised in gardening, in levelling down raised, or filling up hollows, fenses, and in other cases of partially altering a grassy surface.

5715. It is said to have been first used in agriculture by Whitworth, of Acres; house, Lincolnshire; and in 1812 it was brought forward on a large scale by John Blomfield, of Warham, in Norfolk, a tenant of Coke’s Blomfield planted eleven acres in this way. An account of the process, which is styled transplan- ting, or laying land and turf, has been published by Francis Blaikie, Coke’s steward. (On the Conversion of Arable Land into Pasture, 12mo, 1817.)

5716. An abstract of the process of transplanting turf, and an opinion on it, are thus given in The Code of Agriculture. A piece of good clean, sweet old turf, which ought principally to consist of fibrous-rooted plants, is cut up into pieces, square, and then immersed in water, and laid on the surface of ground prepared for that purpose. In this way one acre of turf will plant nine acres of arable land. The pieces of turf should be carefully placed with the grass side uppermost, and the plants pressed well into the ground. No more turf should be cut, carried, and spread in any one day than is likely to be planted before night. If the transplanted turf is found deficient in any particular species of favourite plants, as white clover, permanent red clover, &c., the seeds of those plants should be sown upon the young pasture in April. When the ground is in proper temper (between wet and dry) the pasture should be frequently well trod down by heavy rollers, which will cause the plants to extend themselves along the ground rather than rise into tufts, which otherwise they would be apt to do. No stock should be permitted to feed upon the transplanted pasture in the first spring or summer, nor until the grasses have penetrated the ground. The grazing should be moderate after the first season. Of the same pasture, plants and their young progeny have united and formed a compact turf. The expense of this operation is about £1 10s. per statute acre; without making any allowance for the charges incurred by following the arable land on which the turf has been transplanted; nor for the year’s rent, poor’s rates, and any other expense. But the expense can be saved if the plants are placed in the field before their formation is complete, and immediately after the land which they occupy is left in a barony or fallow state. This plan seems to be well calculated to promote the improvement of light soils, not naturally of a grassy nature; for the grasses and their roots being once formed on a rich soil, will probably thrive afterwards in smaller or more considerable pieces. It will afford a cheap and easy means of securing the atmosphere. For light and gravelly soils, therefore, where permanent pasture is desirable, the plan cannot be too strongly recommended; and if it were found to answer on peat, after the surface was pared for the reception of the plants, and burnt to promote their growth, it would be a most valuable acquisition to the peat districts. Thus for Sir John Sinclair, but from facts related by Sinclair of Woburn, it appears to be a plan of little or no merit, and only brought into notice by its novelty. (H. G. Wob. 2d edit. 420, 421.)

 Sect. III. General View of the Produce, Uses, Character, and Value of the principal British Grasses, according to the Result of John Duke of Bedford’s Experiments at Woburn.

5717. In all permanent pastures, Sir H. Davy observes, nature has provided a mixture of various grasses, the produce of which differs at different seasons. Where pastures are to be made artificially, such a mixture ought to be imitated; and, perhaps, pastures superior to the natural ones may be formed by selecting due proportions of those species of grasses fitted for the soil, which afford respectively the greatest quantities of spring, summer, lattermath, and winter produce; a reference to the results of the Woburn experiments, he adds, will show that such a plan of cultivation is very practicable.

5718. The manner in which these experiments were conducted is thus described:—“Spots of ground, each containing four square feet, in the garden near Woburn Abbey, were marked off with lines common between the earth included by the boards, and that of the gar- den. The soil was removed in these enclosures, and new soils supplied; or mixtures of soils were made in them, to furnish as far as possible to the different grasses those soils which seem most favourable to their growth. Many varieties being adopted for the purpose of ascertaining the exact proportion of the several kinds of grasses required on the same plant. The grasses were either planted or sown, and their produce cut and collected, and dried at the proper seasons, in summer and autumn, by Sir H. Davy, His Grace’s gardener. For the purpose of deter- mining, as far as possible, the relative powers of the different kinds of grasses, equal weights of the dry grasses or vegetable substances were acted upon by hot water till all their soluble parts were dissolved; the solution was then evaporated to dryness by a gentle heat in a proper stove, and the matter obtained carefully weighed. This part of the process was likewise conducted with much address and intelligence by Sir H. Davy, by whom the following results were arrived at. Dry extractions of 5 parts of the nutritive matter of the grasses, were sent to me for chemical examination. The composition of some of them is stated minutely, but it will be found from the general conclusions, that the mode of determining the nutritive power of the grasses, by the quantity of matter that contains soluble in water, is sufficiently accurate in the purposes of the present investigation.” (Agr. Chem. appp.)

5719. The leading results of these experiments we have endeavoured to present in a tabular view; further details will be found in the paragraphs (antecedent and posterior) referred to in the first column. On the other hand, the following results are obtained, that the height is given more by a guess than measurement, and after the appearance of the plants in a state of nature or medium soils. It is to be regretted that the height of the plants was not included in the published details. The time of flowering is given as it took place at Woburn; on which it is observed, that “to decide positively that a grass is coming into flower, the seed, will be found immeasurable; for a variety of circum- stances interfere. Each species seems to possess a peculiar life in which various periods may be distinctly marked, according to the varieties of its age, of the seasons, soils, exposures, and modes of culture.”

5720. The conversion of the uninjured cell to the corn, or caryopsis, is the chief mode by which the dry mat- ter is transformed to vegetable ranks and being, in the least proportion, and the sand and vegetable matter in the greatest. The terms light sandy soil, light brown loam, &c, are varieties of the above, as expressed. The abbreviations of the names of books and native soils, with all abbreviations used in this work, will be found explained in the General Index.

5723. The order in which these substances are nutritive is thus given:— "The albumen, sugar, and mucilage, probably when cattle feed on grass or hay, are for the most part retained in the body of the animal; and the bitter principle, extract, saline matter, and tannin, when any exist, probably for the most part are voided in the excrement, with the undigested food. For the body of the animal is extremely similar in chemical characters to that existing in the soluble products from the grass. And some extract, obtained by Sinclair from the dung of sheep and of deer, which had been feeding upon the L. Íbium perennis, D. Íeltylii glomerata, and Trisilium repens, had qualities so analogous to those of the extract, the dung after being kept for some weeks, had still the odour of hay. Suspecting that some undigested grass might have remained in the dung, which might have furnished mucilage and sugar, as well as the tannin examined, I examined the undigested matter very carefully for these substances, but did not yield an atom of sugar, and scarcely a sensible quantity of mucilage." Sinclair, in comparing the quantities of soluble matter afforded by the mixed leaves of the L. Íbium perennis, D. Íeltylii glomerata, and Trisilium repens, and that obtained from the dung of cattle fed upon them, found their quantities proportional as 40 to 13.

5724. In comparing the composition of the soluble products afforded by different crops from the same grass, Sir H. Davy found, in all the trials, the largest quantity of truly nutritive matter in the crop cut when the seed was ripe, and least bitter extract and saline matter; most extract and saline matter in the autumnal crop, and most saccharine matter, in proportion to the other ingredients, in the crop cut at the time of flowering.

5725. The greater proportion of leaves in the spring, and particularly in the late autumnal crop, accounts for the quantity of extract; and the inferiority of the comparative quantity of sugar in the summer crop probably depends upon the agency of light, which tends always in plants to convert saccharine matter into mucilage or starch. Amongst the soluble matters afforded by the different grasses, that of the Í. Íbium arenarius (Barb. Scwe.) was remarkable for the quantity of saccharine matter it contained. The quantity of the extractive matters obtained from the leaves of the same grass, but at a different time and under different circumstances than those which were used in the present investigation, was almost pure mucilage. The soluble matter of the seed crop of the Í. Íbium pratense, or meadow cat's-tail, afforded more sugar than any of the P. as or Í. Íbium species. The soluble parts of the seed crop of the Holcus mollis, and Holcus lanatus, contained no bitter extract, and consisted entirely of mucilage and sugar. Those of the Holcus odoratus afforded bitter extract, having a pale yellow substance which might be considered to be albumen. All the soluble extracts of those grasses, that are most liked by cattle, have either a saline or subacid taste; that of the Holcus lanatus is similar in taste to gum arabic. Probably the Holcus lanatus, which is so common a grass in meadows, might be made palatable to cattle by being sprinkled over with salt.

5726. No difference was found in the nutritive produce of the crops of the different grasses cut at the same season, which would render it possible to establish a scale of their nutritive powers; but probably the soluble extractive matter is always from one crop to another from the flower or seed crop. In the aftermath the extractive and saline matters are certainly usually in excess; but the aftermath hay mixed with summer hay, particularly that in which the fox-tail and soft grasses are abundant, would produce an excellent food.

5727. Holcus odoratus Had. G. A. — The proportional value which the grass, at the time of flowering, bears to that at the time the seed is ripe, is as 4 to 13. The proportional value which the grass of the aftermath bears to that at the time the seed is ripe, is nearly as 9 to 13.

5728. The grass of the aftermath, and that of the crop at the time of flowering, taking the whole quantity, and their relative proportions of nutritive matter, are in the following proportion. The value of the grass at the time of flowering is as 6 to 10; the value of the aftermath is 5 to 17. This makes the proportion of the lattermost in proportion as 5 to 17. Though this is one of the earliest of the flowering grasses, it is tender, and the produce in the spring is incomparable. If, however, the quantity of nutritive matter which it affords be compared with that of any of those species which flower later in the same season, it will be found greatly superior. It sends forth beautiful flowers, which, if they succeed, make the naturalists so much as to prevent it from flowering for that season; otherwise, the quantity of nutritive matter which the grass affords (for the straws are very incomparable) would rank it as a valuable grass for permanent pasture.

5729. Arenaria pubescens E. B. (Trisilium pubescens E. F. of P. 1670.) — The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe, is as 6 to 8. The proportional value which the grass of the aftermath bears to that at the time of flowering is as 6 to 10; that of the seed-crop, and that of the aftermath, are of equal value. The downy hairs which cover the surface of the leaves of this grass, when growing on poor light soils, almost entirely disappear when it is cultivated on a rich soil.

5730. Poa ciliata var. pratensis E. B. — If the produce of this variety be compared with that of
WOBURN

Poa pratensis, it will be found less; nor does it seem to possess any superior excellence. The superior nutritive power does not make up for the deficiency of produce by 80 lbs. of nutritive matter per acre.

5732. Festuca hordifloris H. Cant. — This is rather an early grass, though later than any of the preceding species: its foliage is very fine, resembling the F. duriuscula, to which it seems nearly allied, differing however in the colour of the flowering plant. The common name is given to it, and the nutritive powers it affords, to possessed, joined to its early growth, are qualities which strongly recommend it for further trial.

5733. Festuca cumbria Curs. — The proportional value of the grass at the time of flowering exceeds that at the time the seed is ripe as 6 to 12. The proportional difference in the value of the flowering and seed crops of this grass is directly the reverse of that of the preceding species, and affords another strong proof of the value of the straws in grass crops, which is largely exceeded for hay. The seed is large, and, from that period till the seed be perfect, they gradually become dry and wiry. Nor do the root-leaves sensibly increase in number or in size, but a total suspension of increase appears in every part of the plant, the roots and seed-vessels excepted. The straws of this species are particularly early on the market, at the time of flowering, weak and tender; but as they approach towards the period of ripening the seed, they become firm and succulent; after that period, however, they rapidly dry up, and appear little better than a more dead substance.

5734. Festuca globosa With. B. — The proportional value of which the grass at the time of flowering bears to that at the time the seed is ripe bears as 5 to 8. The proportional value of which the lattermathe bears to that of the crop at the time of flowering, is as 2 to 5; and to that of the crop, at the time the seed is ripe, as 2 to 5. The general appearance of this grass is similar to that of the Festuca duriuscula; it is, however, specifically different, and inferior in many respects, which will be manifest on comparing their several produce with each other; but if it be compared with some others, now under general cultivation, the result is much in its favour, the soil which it affects being duly attended to.

5735. Festuca viridia With. B. — The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe is as 6 to 8. This species is smaller in every respect than the preceding. The leaves are seldom more than from three to four inches in length; it affects a soil similar to that favorable to the F. duriuscula; and which it would clearly appear on a comparison of their produce with each other. The proportional value which the lattermathe bears to that at the time the seed is ripe is as 6 to 8, and is of equal value with the grass at the time of flowering.

5736. Festuca ovina E. B. — The dry weight of this species was not ascertained, because the smallness of the produce renders it entirely unfit for hay.

5737. Festuca cumbria Hud. — This species is nearly allied to the Festuca ovina, from which it differs little in the general character, that it is larger in every respect. The produce, and the nutritive matter which it affords, will be found superior to those given by the F. ovina, if they are brought into comparison.

5738. Brmnus diurnus Curt. Lend. (B. maritima E. of P. 1140.) — This species, like the Festuca cumbria, is strictly superior to the produce which that of the former possesses of the perennial grasses, will be found inferior, and must consequently be regarded as unworthy of culture.

5739. Poa angustifolia With. 2. — In the early growth of the leaves of this species of Poa, there is a strong indication that early flowering grasses is not always connected with the most abundant early produce of leaves. In this respect, all the species which have already come under examination are greatly inferior to that now spoken of. The culms are most valuable for the manufacture of the finest straw plait.

5740. Avéna elata Curt. (Holcus arenacous E. of P. 1427.) — This grass sends forth straws during the whole season; and the lattermathe contains nearly an equal number with the flowering crop. It is subject to the rust, but the disease does not make its appearance till after the period of flowering, and affects the whole plant, and at the time the seed is ripe the leaves and straws are withered and dry. This accounts for the superior value of the lattermathe over the seed crop, and points out the propriety of taking the crop when the grass is in flower.

5741. Poa elata Curt. — The botanical characters of this grass are almost the same as those of the Avéna elata, differing in the want of awns only. It has the essential character of the Holci (foros, male and hermaphrodite; calyx husks two-valved, with two foros; and since the Avéna elata is now referred to that genus, this may with certainty be considered a valuable species.

5742. Brmnus arenacous E. B. — The common name which the grass at the time the seed is ripe bears to that at the time of flowering, is as 6 to 11 nearly. The proportional value which the grass of the lattermathe bears to that at the time of flowering, is as 3 to 14; and to that at the time the seed is ripe as 6 to 11. This species, in a favourable opinion was given, was spoken of the F. hordeiformis, and F. globosa. (5732, and 5734.) Its produce in the spring is not very great, but of the finest quality, and at the time of flowering is considerable. If it be compared with those affect.

5743. Milium effusum. — This species in its natural state seems confined to woods as its place of growth; but the trial that is here mentioned concerns the opinion that it will grow and thrive in open exposed situations. It is remarkable for the lightness of the produce in proportion to its bulk. It produces foliage early in the spring in considerable abundance; but its nutritive powers appear comparatively little.

5744. Poa maritima E. B. — The proportional value which the grass of the lattermathe bears to that at the time of flowering of itself, is as 4 to 7.

5745. Poa pratensis E. B. — The proportional value which the crop, at the time the seed is ripe, bears to that at the time of flowering, is as 4 to 9.

5746. Brmnus multiflorus E. B. — This species is annual, and no valuable properties have as yet been discovered in it. The common name of it is only an account of its being frequently found in poor grass lands, and sometimes in meadows. It appears, from the above particulars, to possess nutritive powers equal to some of the best perennial kinds, if taken when in flower; but if left till the seed be ripe (which, from its early growth, is frequently the case), the crop is comparatively of no value, the leaves and straws being then completely dry.

5747. Festuca lolliacea Curt. Lend. — The proportional value which the grass, at the time of flowering bears to that at the time the seed is ripe, is as 12 to 13; and the value of the lattermathe stands in proportion to that of the straws, as 5 to 12, and to that of the crop taken at the time the seed is ripe, as 5 to 13. This species of Festuca greatly resembles the ryegrass, in habit and place of growth; it has excellences which make it greatly superior to that grass, for the purposes of either hay or permanent pasture. This species seems to improve in produce in proportion to its age, which is directly the reverse of the Lolium perenne.

5748. Poa cristata Host, G. A. — The produce of this species, and the nutritive matter which it affords, are equal to those of the Festuca ovina, at the time the seed is ripe, they equally delight in dry soils. The grass possesses the lattermathe, with the comparative coarseness of the foliage, renders the Poa cristata inferior to the Festuca ovina.

5749. Festuca Myurus E. B. (Agrostis crus-galius E. of P. 118.) — This species is strictly annual; it is likewise subject to the rust; and the produce being but little, it ranks as a very inferior grass.

5750. Festuca calamifolia E. B. — The proportional value which the grass, at the time the seed is ripe, bears to that at the time of flowering, is as 12 to 18. This grass, as has already been remarked, produces

3

1

2
a fine early foliage in the spring. The produce is very great, and its nutritive powers are considerable. It appears, from the above particulars, to be best adapted for manure. It is a very singular disease for facilitating the growth of so many other species; for the cause of this disease seems to be unknown; it is denominated clausus by some; it appears by the seed swelling to three times its usual size, in length and thickness, and the want of the coricle. Dr. Willoby describes two distinct species of it: first, the simple clausus, which is a faintly and of a dusky yellow, without an actual color; the latter is a mottled clausus, and of greater pungent taste. Bread made from grain infected with this last species, is of a bluish colour; and when eaten, produces cramps and giddiness.

The proportionate value which the grass, at the time of flowering, bears to that at the time the seed is ripe, is as 6 to 14. This species greatly resembles the preceding, in habit and manner of growth; but is inferior to it in value, which is evident from the description of the latter. It will flourish in the muddy soil and in proportion to its weight. The seed is afflicted with the same disease that destroys that of the former species.

573. Poa festuca Host. G. A. — If the nutritive powers of this species be compared with any other of the same family, or such as resemble it in habit and soil which it affects, a superiority will be found, which ranks this as one of the most valuable grasses. Next to the Poa angustifolia, it produces the greatest abundance of early foliage, of the best quality, which fully compensates for the comparative lateness of flowering.

574. Arundo colorata Hort. Kew. — The strong nutritive powers which this grass possesses recommend it to the notice of occupiers of strong clayey lands which cannot be drained. Its produce is great, and the foliage will not be denominated coarse, if compared with grasses which afford a produce equal in quantity.

575. Hordeum pratense E. B. — The specific characters of this species are much the same as those of the Poa festuca, differing from it in the compressed figure of the culms, and in the quality of its grain. It would therefore, be one of the most valuable grasses; for it produces foliage early in the spring, and possesses strong nutritive powers.

576. Agrostis gigantea Curt. Lond. (Glyceria fluitans E. P. of 1699).—The above produce was taken from a species of grass that had occupied the ground for four years; during which time it had increased every year. It appears, therefore, contrary to what some have supposed, to be capable of being cultivated in perennial pasture.

577. Poa festuca var. 2. Host. G. A. — The proportionate value which the grass, at the time of flowering, bears to that at the time the seed is ripe, is as 12 to 20. The proportionate value which the grass of the latter then bears to that at the time of flowering, is as 6 to 12; and to that at the time the seed is ripe, as 6 to 20.

578. Phleum nodosum Wither. — This grass is inferior in many respects to the Phleum pratense. It is sparingly found in meadows. From the number of bulbs which grow at the base of the stems, a greater portion of the produce of this species may be expected. It is a mottled clausus, and of the oil yields, as the joints, which are so conspicuous in the Phleum pratense, the nutritive powers of which exceed those of the P. nodosum as 8 to 28.

579. Phleum Wither. — This is one of the most common of the hents, and likewise the earliest; in these respects it is superior to all others of the same family, but inferior to several of them in produce, and the quantity of nutritive matter it affords. As the species of this family are generally rejected by the cultivator, on account of the lateness of their flowering; and this circumstance, as has been shown, is of the greatest consequence, very few, if not all, always imply a proportional lateness of foliage, and nutritive merit in this respect may be better seen, by bringing them into one view, as to the value of their early foliage.

The apparent Difference of Time.

| Agrostis villosa | October | | 1550 | | 1550 |
|----------------|--------|-------------|--------|-------------|
| poeustris      | October | | 2150 | | 2150 |
| stolonifera    | October | | 2150 | | 2150 |
| striata        | October | | 2150 | | 2150 |

580. Phleum sanguinole E. B. — This species is strictly annual; and from the results of this trial, its nutritive powers appear to be very inconsiderable.

581. The grasses which afford the best culms for straw plate are, according to Sinclair, as follows: —

| Grasses         | 2. | | 3. | | 4. |
|----------------|---|-------------|---|-------------|
| Poa tomentosa   | 2. | | 3. | | 4. |
| Poa annua, duriuncal, and hor- | | | | |
| defferens, Xanthium stricta. | | | | |

582. The period for cutting the culms is when they are in blossom. They are bleached by pouring boiling water over them, in which they remain ten to fifteen hours, or as long as seven or eight days. Sinclair found that by letting the culms remain in hot water from one to two hours, or only three or two days bleaching was required. When bleached, they are taken up, washed clean, and put in a moist state in a close vessel, where they are subjected to the fumes of burning sulphur. After this treatment, and then subjected to the sulpherous acid gas, are bleached perfectly white in half an hour. Green culms, immersed for fifteen minutes in uratite acid, diluted with twenty times its measure of water, and then spread on the grass, become yellow as perfectly bleached as those which were scalded and bleached eight days on the grass. The texture of the straw was not the least injured by these processes. The application of the sulpherous acid gas to the meistened culms, even after scalding and bleaching on the grass, had, in every instance, the effect of greatly improving the colour, and that without being productive of the smallest injury to the texture of the straw. (Hort. Gram. Wob. 3d edit. 47.)
To initiate the Leghorn plait in the most perfect manner, the straws should be plaited the reverse way of the common English split-straw plait. In the English plait, the straws are flattened by a small hand-mill made for the purpose: but the Leghorn plait has the straws worked without flattening, and pressure is applied after the plait is severed. It is said that these two points should be observed by those who wish to rival the finest Leghorn manufacture. By reversing the common mode of plaiting, the fingers have a much greater power in firmly and intimately knitting the straws; and the round or un-flat straws allows of their being more closely knitted, — a circumstance that gives an appearance similar to the real Leghorn plait. (Ibid.) The varieties of wheat or rye already mentioned (5602. and 5607.) are now generally considered far preferable to any of the forage grasses for the purpose of straw plait.

**Book VI. MEADOW LANDS.**

5766. To initiate the Leghorn plait in the most perfect manner, the straws should be plaited the reverse way of the common English split-straw plait. In the English plait, the straws are flattened by a small hand-mill made for the purpose; but the Leghorn plait has the straws worked without flattening, and pressure is applied after the plait is severed. It is said that these two points should be observed by those who wish to rival the finest Leghorn manufacture. By reversing the common mode of plaiting, the fingers have a much greater power in firmly and intimately knitting the straws; and the round or un-flat straws allows of their being more closely knitted, — a circumstance that gives an appearance similar to the real Leghorn plait. (Ibid.) The varieties of wheat or rye already mentioned (5602. and 5607.) are now generally considered far preferable to any of the forage grasses for the purpose of straw plait.

**CHAP. VII.**

Management of Lands permanently under Grass.

5767. In every country by far the greater proportion of perennial grass lands is the work of nature; and it is not till an advanced period in the progress of agriculture that much attention is paid to their management. But as the extension of tillage, planting, and the formation of parks and gardens, limit the range of the domestic animals, their food becomes more valuable; and it then becomes an object to increase it by the culture of roots and artificial herbage on some lands, and by the improved management of the spontaneous productions of others. In a highly cultivated country like Britain, therefore, those lands retained in grass either are, or ought to be, such as are more valuable to the owners in that state than they would be in any other. Such lands naturally divide themselves into two classes; those which are fit either for mowing or pasture; and those which are fit for pasture only.

**SECT. I.** Perennial Grass Lands fit for mowing, or Meadow Lands.

*5768. Under the term meadow, we include all such land as is kept under grass chiefly for the sake of a hay crop, though occasionally, and at particular seasons of the year, it may be destitute by the domestic animals; and we usually include under this term the notion of a greater degree of moisture in the soil, than would be thought desirable either for permanent pasture or lands in tillage. Where hay is in great demand, as near large towns, and especially if a good system of cropping is but little understood, a great deal of arable land may be seen appropriated to hay-crops; but the most valuable meadows are such as are either naturally rather moist, or are rendered so by means of irrigation. There are three descriptions of these meadows: those on the banks of streams and rivers; those on the uplands, or more elevated grounds; and bog-meadows; and each of these kinds may be stocked with grasses, either naturally or by art, and may be irrigated by one or other of the different watering processes already described.

5769. River-meadows, or those which are situated in the bottoms of valleys, are in general by far the most valuable. They are the most productive of grass and hay, yielding sustenance for cattle through the summer and the winter, and producing an everlasting source of manure for the improvement of the adjoining lands.

5770. The soil is deep, and commonly alluvial, having been deposited by water, or washed down from the adjoining eminences; the surface is even, from the same cause; and, what is of considerable importance, it has a gradual declivity or surface-drainage to the river or stream which almost invariably flows in the lowest part of every valley, and which is essential to this description of meadow. The principal defects to which such lands are liable are, the eoozing out of springs towards their junction with the rising lands, and the inundations of the river or stream. The former evil is to be remedied by under-draining, and the latter by embanking. Such meadows are generally stocked with the best grasses; and their culture consists of little more than forming and keeping open a sufficient number of surface-gutters or furrows to carry off the rain-water; rooting out such tufts of rushes, or bad grasses and herbage, as may occasionally appear; destroying moles, and spreading the earth they throw up; removing heavy stock whenever their feet touch the surface; shutting up, bush-harrowing, and rolling at the commencement of the growing season; and finally so adjusting the mowing and pasturing as to keep the land in good heart without laying on manure.

5771. The most suitable meadows for irrigation are of this description; the necessary drains and other works are cheap and easy, and generally produce great savings of expense; and the management, as we have seen, 1580., is also comparatively easier than in watering sloping surfaces.

5772. Upland meadows, or moving lands, are next in value to those of valleys.

5773. The soil is either naturally good, and well adapted for grass, or, if inferior by nature, it is so situated as to admit of enrichment by ample supplies of manure. Of this last description are the upland meadows or hay lands of Middlesex; which, though on the most tenacious, and often stony chays, are yet, by the abundance of manure obtained from the metropolis, rendered as productive as the best upland soils employed as hay lands. The roots of perennial grasses, whether throns or creeping, never strike deep into the soil; and thus, deriving their nourishment chiefly from the surface, top-cressings, of well-rotted manure, repeated on the same field for centuries, form at last a thin black stratum among the roots of the grass, which produces the most luxuriant crops.

5774. The culture of upland meadows requires more attention and expense than that of valleys; being more difficult to drain, and requiring regular supplies of manure. The irregular surface of uplands is apt either to contain springs or to stagnate the surface water; the first produce marsh plants and coarse herbage, and the latter destroys or weakens whatever is growing on the surface, and encourages the growth of moss. Both evils are to be remedied by the obvious resources of drainage. Moss is a very common enemy to grass lands, and is only to be effectually destroyed by rich dressings of manure. Rolling, and top-dressings of lime and salt, have been recommended for destroying it; but there is no mode by
which it can be subdued and kept under, but by adding strength to the grass plants, and thereby enabling them to subdue their enemy. Moss is never found on rich lands unless they are completely shaded by trees. Besides mole-hills, upland moor, and neglected lowlands, when not regularly kept down, are frequently troubled with ants, which form regular hillocks of grass and earth, more injurious and more difficult to get quit of than those of moles. The mode of taking moles is a simple operation, and will be described in the proper place; that of destroying ants is more complicated and tedious, and, being peculiar to grass lands, shall here be described.

577. Ant-hills, or habitation districts, are injurious to meadow lands, by depriving the farmer of a crop in proportion to the surface they occupy, and by interfering with the operations of rolling and mowing. They consist of little mounds or piles of small particles of earth, which may in some instances be computed at a tenth part, or more, of old grass lands. In some places, where negligence has suffered them to multiply, almost half the land has been rendered useless; the hills standing as thick together as grass-rocks in a hay-field; and whereas it is evident, that the area occupied by these little sacrilegious spots of their land is thereby increased; whereas it is well known that very little or no grass ever grows thereon, and, therefore, if the surface is increased, the produce is proportionately decreased.

578. To remove for destroying ant-hills, and destroy the insects, it has been a custom in some places, at the beginning of winter, and often when the weather was not very cold, to dig up the ant-hills three or four inches below the surface of the ground, and then to cut them in pieces, and scatter the fragments about; but this practice only disperses the ants, instead of destroying them, as they hide themselves in the roots of the grass for a little time, and then collect themselves together again upon any little eminence, of which there are great numbers ready for their purpose, such as the circular ridges round the hollows where the hills stood before. It is, therefore, a much better method to cut the hills entirely off, rather lower than the surface of the land, and to let them lie whole at a little distance, with their backs upward; by this means the ants, which are known to be very tenacious of their abodes, continue in their habitations until the rains, by running into their holes of communication, and stagnating in the hollows formed by the removal of the hills, the ants die, the frosts, which immediately follow, soon rendered, or laid on the places, and washed in with the rains, it would probably contribute greatly to the intended effect. The hills, when rendered mellow by the frosts, may be broken and dispersed about the land. By this method of cutting the hills, one other advantage is gained; the land soon becomes even and level, and the breezy winds, which once being removed, not only render it more convenient, but very disagreeable and destructive to them. It would, perhaps, be a better practice than that of suffering the hills to remain on the ground, to collect the parts of them which have been pared off into a heap, in a convenient place, and, when composted, throw them into a dunghill with the rest.

In wet weather these insects are apt to accumulate heaps of sandy particles among the grass, called by labourers sprout-hills, which quickly take off the edge of the sycy. These hills, which are very light and compressible, may be conveniently removed by frequent horse rolling.

579. The cutting and burning of ant-hills. The process is, to cut them up with a heart-shaped spade or shovel, in irregular lengths of from ten to fifteen inches in diameter, and from two to five or six inches thick. These are to be turned the grass-side downwards, until the mould-side is thoroughly dry, and then to be sent to the grass-side outward, so that they may be kept, dried, and burnt, in a form. This way of treating them, will render their destruction, not only more certain, but you may change better circumstances, which, in some cases, do not neglect, on grounds where such a process is required.

580. When can a turfing iron make two cuts across the hill at right angles to each other; then turn back four quarters thus obtained from the hill, leaving it bare; next cut out and throw to a distance the interior earth of the hill with all the ants; turnin their winter's board of provision, as well as all their effects, to the very bottom. Now remove the destruction of the ants, this is a ready, though by no means an economical, way of raising manure, and in some cases ought not be neglected, on grounds where such a process is required.

581. Where grass lands are sufficiently rolled with a heavy roller once or oftener every year, no ant-hills will ever be formed greater than the roller can compress, and consequently no injury will be sustained. In this, as in most other cases of disease, proper regimen is the cure. In the best economy, various directions are given for destroying hogs, lice, and other vermin; but who ever had any to destroy, who attended to its early to cleanliness !

582. The surface of some grass lands that have been long rolled is apt to get into that tenacious state denominated hide bound. When this is the case, scarifying the turf with a plough, consisting only of cold teeth, or, in preference to all others, their teeth to all other to the very bottom, only so that the whole surface may be cut or torn, is to be recommended. That tenacious state, rolling tends to increase; whereas, by scarifying, the surface is loosened, and the roots acquire new means of improved vegetation. This operation seems particularly useful, when it precedes the manuring. When hay land of a retentive quality is depastured by cattle or horses in wet seasons, it receives much injury from their feet, and becomes what is technically called poached. Every step they take leaves an impression, which fills with rain water, and then the hole stands full like a cup. This wetness destroys the herbage, not only in the hole, but that also which surrounds it, while at the same time the roots of the grasses, as well as the ground, are chilled and injured. No good farmer, therefore, will permit any cattle to set a foot on such land in wet weather, and few during the winter months, on any consideration. Sheep are generally allowed to graze grass over, from the month of October to the month of March; but when they are then removed, and it rarely happens that any animal is admitted till the weather is dry, and the surface so firm as to bear their pressure without being poached or injured.

583. In manuring upland meadows, the season, the sort, the quantity, and the frequency of application are to be considered.

584. With regard to the season at which manure should be applied, a great difference of opinion prevails among the farmers of England. In the county of Middlesex, where almost all the grass lands are preserved, the manure is usually laid on in October (Moore Report, p. 52), while the land is sufficiently dry to bear the driving of loaded carts without injury, and when the heat of the day is so moderate as not to excite the volatile parts of the dung. Others prefer applying it immediately after the harvest; and others, at the end of July to the end of August (Com. to Board of Agriculture, vol. iv. p. 158); and if that season is inconvenient, any time from the beginning of February to the beginning of April. (Dickson's Practical Agriculture, vol. ii. p. 915.) It is, however, too common a practice to carry out the manure during frosty weather, when, though the ground is free, the rolling parts of the dung are dissipated, and washed away by the snow and rains before they can penetrate the soil.

585. There is scarcely any sort of manure that will not be useful when laid on the surface of grass grounds in general; those of the more richly cultivated, as those of the meadows and meadow lands; and dung, in composition with fresh vegetable earthy substances, the most useful in the new leys or grass lands. In Middlesex it is the practice of the best farmers to prefer the richest dung they can procure, and seldom to mix it with any sort of earthy material, as they find it to answer the best with regard to the quantity of produce, which is the principal object in view; the cultivators depending chiefly for the
salve of their hay in the London markets. It is the practice to turn over the dung that is brought from London to a tolerable state of rottenness, once chopping it well down in the operation; so as to be in a much more salvable state. It is also necessary to put in fresh, green, and rotten and reduced state when applied in the spring, than when the autumn is chosen for that purpose.

(Dickson's Practical Agriculture, vol. ii. p. 915.)

5784. Some interesting experiments have been made with different kinds of manure, for the purpose of ascertaining their effects, with regard to the quantity and quality of the produce of different kinds of land. Fourteen lots, of half an acre each, were thus manured, and the grass was made into hay, all as nearly alike as possible. The greatest weight of hay was taken from the lot manured with horse, cow, and slaughterhouse dung, and the quantity of it, at that state above twenty tons, was then turned over, and allowed to lie for eight or ten days more, after which it was put on the land before it had done fermenting, and spread immediately. To ascertain the quality of the produce of the different lots, a small handful of hay was spread on the dry clean places, and where there was a draw or rutging, six horses were turned out to them one after another. In selecting the lots, there seems to have been little difference of taste among the horses; and all of them agreed in rejecting two lots, one of which had been manured with blubber mixed with soil, and the other with soil, in both instances laid on in the month of April, and produced in July.

(Lauvastria, p. 175.)

5785. The proportion of manure that is necessary must, in a great measure, depend upon the circumstances of the land, and the facility of procuring it. In the district of London, where the manure is of a very high quality, it is introduced in small quantities; other ploughed and productive animals are highly fed, the quantity is usually from four or five to six or seven loads on the acre, such as are drawn by three or four horses, in their return from taking up the hay to town. Dickson's Pract. Agr. vol. ii p. 916.

5786. Manure is laid on at intervals of time more or less distant, according to the same circumstances that determine the quantity of it. Though there are some instances of hay grounds bearing fair crops every year during a length of years, without any manure or any advantage from pasturage, except what the aftergrass has afforded. (Production of Reports to the Board of Agriculture, p. 183 Western Department;) yet, in general, manure must either be allowed every third or fourth year, in the land, kept one year, and mown the other; or, what is better, a pasture two years, and the third. (Northumberland Report, p. 111.) A succession of hay crops without manure, or pasturage, on meadows not irrigated, is justly condemned by all judicious farmers, as a sure means of impoverishing the soil.

5787. Bog meadows are the least valuable of any: they are of two kinds; peat bogs, and earthy bogs.

5788. Peat bogs are situated in hollows or basins, which, from having no natural outlet for water, and not being so deep or so plentifully supplied with that element as to constitute lakes, becomes filled up with aquatic plants and mosses. By the decay of these after a certain time, and the drainage and culture of art, a surface of mossy soil is formed on which growing causes may be sown and grown naturally. In warm moist climates, and mud of the bog is rich, firion or Timothy grass may be found to answer; but in general the woolly soft grass and cock's-foot are resorted to, unless indeed lime be aggers for and woman's including leas, in which cases the choice of grass will sometimes answer. These grasses are in general too soft for pasturing any other animals than sheep.

5789. Earthy bog meadows are situated either in hollows or on slopes. They are formed by an accumulation of water in the subsoil, which, from new passage in any one point, spreads under and filters upwards through the bog. The grasses here are the shortest and the finest; the meadows on the lower parts of the hilly district are generally of this kind, and resemble the bog meadows.

5790. The culture and management of bog meadows differ in nothing essential from those of the river kinds. A lighter roller is used in spring, the greater care is taken in cutting down the latter grass, whether with small or sheep or cattle; and in some cases, in very dry weather in summer, the main drains are dug to facilitate the water, and supply the soil with moisture. No manure is ever given unless in the case of some cultivated peat bogs, which are dressed with earthy or saline mixtures.

5791. As branches of culture common to every description of hay lands may be mentioned, the hay-making, the application of the after-grass, and pasturage. 5792. The making of natural or meadow hay has been carried to greater perfection in the neighbourhood of London than any where else; and it may therefore, with great propriety, be recommended as an example to the rest of the kingdom. The following account of it is drawn from Middleton's Agricultural Survey of Middlesex:

5793. When the grass is nearly fit for moving, the Middlesex farmer endeavours to select the best movers, in number proportioned to the quantity of his grass and the length of time it would be advisable to have it in hand; which having done, he lets it out, either as piece-work, or to be mown by the acre. In the latter way, each man mows from one acre and a half to an acre and three quarters per day; some there are who do two acres per day during the whole season. About the same time lie provides five haymakers; men, women, and children, including loaves, in which cases the choice of grass will sometimes answer. These last are paid by the day, the men attending from six till six, but the women only from eight till six. For an extra hour or two in the evening, when the business requires despatch, they receive a proportionate allowance.

5794. The mowers usually begin their work at three, or five o'clock in the morning, and continue to labour till seven or eight at night; resting an hour or two in the middle of the day. Every hay-maker is expected to come provided with a fork and a rake of his own: nevertheless, when the grass is ready, and the farmers scarce, the farmer is frequently obliged to provide both, but for the most part only the rake. Every part of the operation is carried on with forks, except clearing the ground, which is done with rakes; and loading the carts, which is done by hand.

5795. First day. All the grass mown before nine o'clock in the morning must be cut with a fork, as it will be of a more valuable quality, heat more evenly in the stack, and be more likely to be thoroughly worked into the stack; will be of greater quantity when cut into trusses, and will sell at a better price; for when the grass is suffered to lie a day or two before it is piled up into the stack, the heat and sun, and the interior part is not dried, but will be burnt when mixed, both with bedding, manure, and quantity, which are very material circumstances. Soon after that is done, the rakes are used, to ensure a perfect degree of care and attention; and if, from the number of hands, they are able to turn the whole again, they do so, or at least as much of it as they can, till two or three o'clock; at which time they do it. The first thing to be done after dinner is to make it into what are called single wind rows; and the last operation of this day is to put it into grass crocks.

5796. Second day. The first part of this day commences with folding all the grass that was mown the last day after nine o'clock, and all that was mown this day before nine o'clock. Next, the grass is drawn into swards, for being cut out into staddles (separate plots of five or six yards' diameter). If the crop should be so large as to be made up into the swards, the quality of the grass is much more liable to be impoved, the quantity, which is very material circumstances. Soon after this, the mowers work on, as already described for the first day. This should all be done before twelve or one o'clock, so that the whole, may lie dry, while the work-people are at dinner. After dinner, the first thing to be done is to rake the staddles into double wind rows; next, to
The grass is cut into single wind rows; then the double wind rows are put into knock-cots, and hollowed rows are put into grass cots. This completes the work of the second day.

353. Third day. The grain is then not spread on the ground. A windrow of the dry grass should be made, in which the crop is to be cut and raked and windrows are put into single cots or wind rows. The mowing is now finished. The hay is now prepared for the market. If the weather is fair, the talk in each cot is to be cleaned and speech. If the weather is wet, the day is to be spent in the same way, as it is to be carried on in bad weather, for the mowing should be completed, and the hay should be as dry as possible, so that it will be fit to carry in. In that case the next thing to be done is to rake those which are in single cots, last night into double wind rows; then the double wind rows are put into single cots. The next morning they are put into windrows, and the single windrows into grass cots, so on the preceding day. After this, the hay which was last night in hark-rack, and which has been used for the market, is to be taken; the hay up clean, and also to be put the raking up clean, after which it is to be put into hark-rack, and the single windrows into grass cots, so on the preceding day. After this, the hay which was last night in hark-rack, and which has been used for the market, is to be taken; the hay up clean, and also to be put the raking up clean, after which it is to be put into hark-rack, and the single windrows into grass cots, so on the preceding day. After this, the hay which was last night in hark-rack, and which has been used for the market, is to be taken; the hay up clean, and also to be put the raking up clean, after which it is to be put into hark-rack, and the single windrows into grass cots, so on the preceding day.
will also thrive as well upon it. The quantity recommended is, a peck of salt to a ton of hay. By this application, hay that had been flooded is preferred to cattle to the best hay that had not been salted. 5609. To make hay-tea. Boil at the rate of a handful of hay to three gallons of water, or, if the water be poured boiling hot on the hay, it will answer nearly as well. Give it to the cattle and horses to drink when well tumbled up, and under cover. The milk is then boiled, and under cover, giving it to them blood-warm. This drink is so extremely nutritious, that it nourishes the cattle astonishingly, replenishes the udders of the cow with a prodigious quantity of milk, makes the horse stall plentifully, and keeps him healthy and strong; and by this method one third of the hay will go as far as eight or ten would otherwise do.

The cattle and horses do not seem to like it at first; but if they are kept till very thirsty, they will drink freely of it ever afterwards. The hay, after being used as before mentioned and dried, may be used as litter for horses and cattle; it will make very good manure, and save straw, which is a considerable advantage, especially where there is a scarcity of that article. (Davies's Rep. of Whites.)

5810. The after-grass on all meadows is generally fed off; on firm lands, and in the dry season, by either sheep or heavy cattle; but in the winter only by sheep, unless the soil is so dry as not to be injured by the feet of cows or horses. The feet of the latter are much less injurious than those of the former; but their bite being closer is more apt to tear up the plants, than the bite of the horned tribe.

5811. Cattle are generally removed from meadow lands in Middlesex in November; horses allowed to remain till February. In Lincolnshire, Leicestershire, and on many river meadows, every description of stock is allowed to remain till April, and sheep till May. In some districts, the whole of the after-growth is preserved from every species of stock till the following May, when it is fed off with sheep; but this greatly retards the hay crop for that year. It is evident that a good deal must depend on the farmer's other resources for keep for his stock.

5812. The after-grass, where manure is very abundant, is sometimes mown and made into hay or rotten, a soft and not very nutritious food, given to cows or sheep; but this is reckoned a bad practice, even in the neighborhood where manure may be in abundance. It is also the usage of some to leave the after-grass on the ground without being eaten till spring, when it is said to be preferable, for ewes and lambs, to turnips, cabbages, or any other species whatever of what is termed spring-fed. This mode of management, which is strongly recommended by Young, and in some cases by Marshal also, is unknown in the north; where, this is the opinion in many instances, farming is merely pastoral, with a view to an early spring growth, not to eat the pasture too close before winter, it would be attended with a much greater loss of herbage, than any advantage in spring could compensate, to leave the after-growth of mown grounds untouched till that season.

5813. A system of alternate mowing and feeding is practised on some hay lands, partly to save labour and manure, and partly to subdue mosses and coarse grasses. On some soils even rich grass lands, when annually mown, become subject to weeds; for it tends to encourage moss, and gives advantage to the stronger-rooted grasses, which gradually change, and deteriorate the nature and quality of the herbage. The bottom becomes thin, the white clover disappears, and coarser plants occupy the ground. When this takes place, the pasture should be fed, instead of being mown, for the space of two or three years, until the weeds have been subdued, and the finer grasses reappear.

5814. By adopting the plan of mowing and feeding alternately, a farmer, it is said, may go on longer without the application of manure, but his fields, in the end, will be ruined by it. It is contended, that to maintain a proper quantity of stock, the land must be accustomed to keep it, particularly in the case of sheep: that where land has been used to the sythe, if manured for pastures, it will often produce mere grass; but that grass will not . . . on the bottom. It is evident that where manure be in abundance, it will grow best as it has been accustomed to grow, and will not readily alter its former habits. On the other hand, it is asserted, that many experienced farmers prefer the system of feeding and mowing alternately, as they find that, under that system, the quality and quantity of the grass may have been improved, and the pasture, in the alternate year, has been equally sweet and productive.

Sect. II. Permanent Pastures.

5815. Permanent pastures may be divided into two kinds: rich or feeding lands, and hill or raving pastures. Under the former, we may comprehend all old rich pastures capable of fattening cattle; and under the second, such as are only adapted to rearing them, or are more advantageously depastured with sheep.

Subsect. 1. Rich or feeding Pastures.

5816. Feeding pastures may include such as are equally fit for hay, or for being converted to arable husbandry; their characteristic being, that they are used for feeding stock, and keeping working animals and milch cows in good condition. We mentioned in a former chapter, that pasturage for one year, or for two, or three, is frequently interposed in the course of cropping arable land, to prevent that exhaustion of the soil which is commonly the consequence of incessant tillage crops. The same culture and management recommended here for rich grass lands are equally applicable to them; there being no difference, except that the latter are generally considered less suitable than rich old turf for fattening heavy stock, such as large oxen.

5817. The culture and management of feeding pastures, whether of a few years, or of perpetual duration, may be considered in regard to those necessary operations already noticed under the former sections, such as the extirpation of weeds and noxious herbs, clearing away ant and molehills, the application of manure, the time of stocking, the number of the animals and whether all should be of one or of different species, &c., the extent of the enclosures, and the propriety of cats the herbage close or leaving it always in a rather abundant state; all these are questions which it is scarcely possible to decide in a satisfactory manner, by the application of general rules. They can only be solved,
with any pretensions to utility, by a reference to the particular circumstances of each case; for the practice of one district, in regard to these and other points, will be found quite inapplicable to others where the soil and climate, and the purposes to which the pastures are applied, are materially different.

5818. The weeding of pastures should be regularly attended to. Weeds in pastures injure the farmer by the ground they occupy, the seeds they disperse, and sometimes, by influencing the quality of milk, or the health of the cattle.

5819. On the large scale of a farm small creeping weeds cannot be removed; but large perennial plants, such as the dock, fern, nettle; and biennials, such as the thistle, and ragweed; together with rushes and coarse tufts or tu-socks of tall-out-grass, should never be permitted to shoot up into flower. The dock ought to be taken out by the root with the dock-weeder, and the others cut over with spadils or spuds. Nettles may be mown over, as may some other weeds, and some descriptions of rushes; fern is most effectually killed by bruising or twisting asunder the stem, when the frond or herb is nearly fully panned. Smaller weeds may be mown, and this operation should never be deferred later than the appearance of the flowers. Where the sloe-thorn forms part of the enclosure hedges, or the English elm, hoary poplar, and some other trees, grow in or around the field, they are apt to send up suckers; these should be pulled up, otherwise they will soon become a serious nuisance. In some parts of England, especially in the central districts, the hedge wastes, from the spread of the sloe-thorn and creeping rose (Rosa arvensis), are sometimes six or ten yards in width.

5820. To prevent the growth of mosses is one of the greatest difficulties in the management of old pasture land; by these the four species of grasses are apt to be overwhelmed, and the coarse sorts only remain. Grass and the use of rich composts, are in this case necessary. Harrowing and cross harrowing with a common harrow, or with what are called grass harrows (Fig. 785), which go from one to two inches deep, with a sprinkling of grass-seeds afterwards, and some lime or well prepared compost, are the most likely means of destroying the moss, and improving the pasture. Feeding sheep with oil-cake, and allowing them to pasture on the land, has also been found effectual for the destruction of moss, and bringing up abundance of grass. But the radical remedy is to plough up such grass lands upon the first appearance of moss, or before it has made any considerable progress, and sow them with corn.

5821. The removal of ant and mole hills should be attended to during the whole summer. The manner of destroying ants has already been described; mole-hills spread on grass lands may be considered as of service rather than otherwise. These operations, together with weeding, and spreading the manure dropped by the larger stock, should go on together at intervals during the whole summer.

5822. The application of manures to grazing lands, which not being used as hay grounds afford no means of supply, may certainly be considered a preposterous practice, and one that must be ruinous to the other parts of a farm.

5823. In the Code of Agriculture it is nevertheless stated, that "to keep grass in good condition, a dressing of from thirty to forty cubic yards or cart-loads of compost is required every four years. The application of unmixed putrescent manure will thus be rendered unnecessary, which ought at least to be avoided, in meadows appropriated for the feeding of dairy cows, from its affecting the quality of the milk" (p. 476). Grass lands kept at an expense of this kind will seldom, it is believed, be found to remunerate a farmer sufficiently. The same thing is recommended (probably from inadvertence or more following the track of preceding writers) in Dickson's Practical Agriculture, vol. ii. p. 355. But, except the dung dropped by the pasturing animals, which should always be regularly spread from time to time, it may be laid down as a rule of pretty extensive application, that if grass lands do not preserve their fertility under pasturage, they must be better to bring them under tillage for a time, than to enrich them at the expense of land carrying crops of corn. (Sup. &c. art. Agr.)

5824. Trenching or stocking on the field, or carrying to be consumed there during winter, the provender that ought to have furnished disposable manure for the use of the farm at large, is another practice not less objectionable. It is to no purpose that such a wasteful practice is defended on dry light soils, which are alleged to be thus benefited by the treading of the cattle. (Marshall's Rural Economy of Yorkshire, vol. ii. p. 153.) During the frequent and heavy falls of rain and snow in winter, there is scarcely any land so dry as not to be injured by the treading of heavy cattle; and were there any thing gained in this respect by this management, it would be much more than counterbalanced by the loss of a great part of the manure, from the same cause. The able writer to whom we have just now referred very properly disapproves of cultivating manure in winter; and for the same reason, namely, the loss of it, which must necessarily be the consequence, he ought to have objected to foddering on the land, or teething at that season. The practice, however, is but too common in those districts, both in South and North Britain, where the knowledge of correct husbandry has made but little progress. It is equally objectionable, whether the fodder is consumed on meadows where it grew, or on other grass lands. The fodder should, in almost every instance, be eaten in houses or fold-yards, instead of the dung being dropped irregularly over the surface; or, as must be generally the case, accumulated in some spots sheltered by trees and hedges, to which the animals necessarily resort during the storms of winter.

5825. The time of stocking pastures in spring must evidently be earlier or later, according to the climate, and in the same climate according to the season; and the state of
growth, which it is desirable that the grass should attain before being stocked, must in some degree be determined by the condition and description of the animals to be employed in consuming it; whether they are only in a growing state or approaching to fatness; whether milch cows or sheep, or a mixture of animals of different species. It conveys no very precise idea respecting these points, though the remark itself is just, to say that the herbage should not be allowed to rise so high as to permit the coarser plants to run to seed; and that it is bad management to suffer store stock to be turned upon a full bite. (Marshall's Yorkshire, vol. ii. pp. 129.)

5826. The great objects to be aimed at are, that the stock, of whatever animals it may consist, should be carried forward to a certain purpose of their owner, and that no part of the herbage should be allowed to run to waste, or be unprofitably consumed. But nothing but careful inspection of the land and of the stock, from time to time, can enable any grazer with certainty what are the best measures for attaining these objects. Fatting the oxen, says Marshal, "which are so prevalent in the Lincolnshire, may require a full bite at first turning out; but for cows, working oxen, and rearing cattle intended to be fattened on grass, a full bite at the first turning out is not requisite. Old Lady-day to the middle of April, according to the progress of spring, appears to me, at present, as the best time for shutting up mowing grounds and opening pastures." (Marshall's Yorkshire, vol. ii, pp. 152, 153.)

5827. In regard to the state of the growth of pastures when first stocked, some distinction should be made between new leys and old close stovers. To prevent the destruction of the young points, whether of clover or the herbage, on the former description of pasture, which would be the consequence of stocking them too early, especially with sheep, they should be allowed to rise higher than would be necessary in the case of old turf; and to secure their roots from the further injury of a hot summer, it is advisable not to feed them. But in the early part of the season, and probably not at any time throughout the whole of the first or second season, it the land is to be continued in pasture. The roots of old and firm sward, on the other hand, are not in so much danger, either from close feeding or from the heats of summer; and they are in much less danger from the frosts and thaws of winter.

5828. With regard to the stock which should be employed, all soils rather moist and of such a quality, as is the case with rich clays, as to produce herbage suited to the fattening of cattle, will, in general, be more advantageously stocked with them than with sheep: but there can be no other rule for the total exclusion of sheep, than the danger of the rot; nor any other general rule for preferring one kind of stock to another, than their comparative profits. (Sup. art. Agr.)

5829. Whether the stock should be all of one or of different kinds is another question to be discussed.

5830. With regard to a mixed stock, the sentiments and practice of the best graziers seem to be in its favour. "It is generally understood that horses and cattle intermixed will eat grass cleaner than any species will alone, not much from their separately affecting different grasses, as from the circumstance of both species dislike to feed near their own dung." (Marshall's Yorkshire, vol. ii. p. 154.) "Some few pastures, then, on the condition of keeping only one kind of stock upon the same ground, whilst others, we think, with more propriety, intermix with oxen and cows a few sheep, and two or three colts in each pasture, which turn to good account, and do little injury to the grazing cattle. In some cases sheep are a real benefit, by eating down and destroying the ragwort (Senecio Jacobaea), which disfigures some of the better pastures of the county, where oxen only are grazed." (Northumberland Report, p. 155.) In Lincolnshire, where grazing is followed to a great extent, and with uncommon success, as well as in most other districts, the practice seems to be almost invariably, to keep a mixed stock of sheep and cattle on the same pasture. (Lincolnshire Report, p. 174.), in proportion varying with the nature of the soil and the quality of the herbage.

5831. To estimate the number of animals that may be depastured on any given extent of ground is obviously impossible, without reference to the particular spot in question; and the same difference exists with regard to the propriety of feeding close, or leaving the pastures rough, that prevails in most other parts of this subject. Though there is loss in stocking too sparingly, the more common and dangerous error is in overstocking, by which the summer's grass is not unfrequently entirely lost. On rich pasture lands in the neighbourhood of Banbury, in Oxfordshire, one ox and two sheep are calculated as stock sufficient for one acre.

5832. With respect to the size of enclosures, small fields are much to be preferred to large ones, for heavy stock.

5833. Besides the advantages of shelter, both to the animals and the herbage, small fields enable the grazer either to separate his stock into small parcels, by which means they feed more at their ease, or to give the best pastures to that portion of them which he wishes to fatten. The small fields are generally found to be the best grazing counties; but the subdivisions are in some instances much more minute than is consistent with the value of the ground occupied with fences, or necessary to the improvement of the stock. In all cases, says Marshal, where fattening cattle or dairy cows make a part of the stock, care should be taken that the grazing soil, and water will permit, every suit of grazing grounds ought, in my idea, to consist of three compartments; one for head stock, as cows or fattening cattle; one for followers, as rearing and other lean stock; and the third to be shut up to freshen for the leading stock. (Marshall's Yorkshire, vol. ii. p. 130.)

5834. Large enclosures are in general best adapted for sheep. These animals are not only impatient of heat and liable to be much injured by flies, in small pastures often surrounded by trees and high hedges, but they are naturally, with the exception perhaps of the Leicester variety, much more restless and easily disturbed than other breeds of sheep, says Lord Rotheram, "I would have a wider range and ought to have it; because they delight in short grass: give them eighty or ninety acres, and any fence will keep them in; confine them to a field of seven or eight acres, and it must be a very strong fence that keeps them in." (Gentleman Farmer, p. 285.) Though fields so large as eighty or ninety acres will have no effect on most districts, yet the general rule is nevertheless consistent with experience, in regard to all our best domesticated varieties.

5835. With respect to the propriety of eating the herbage close, or leaving it rather in an abundant state, an eminent agriculturist observes, that there seems to be a season, some time during the year, when grass lands, particularly old turf, should be eaten very close,
not merely for the sake of preventing waste, but also for the purpose of keeping down the coarser kinds of plants, and giving to the pastures as equal and fine a sward as possible.

5835. The most proper period must partly depend upon the convenience of the grazier; but it can hardly be either immediately before the drought of summer or the frost of winter. Some time in autumn, when the ardent heat of the season is over, and when the greater part of the grass is killed by frost, and generally also for the grazier, his fat stock being then mostly disposed of, or carried to the after-grass of mown grounds. The sweeping of pastures with the scythe may be employed as a substitute for this close feeding; the waste and labour of which, however, though lost really, it does not seem necessary to incur on rich grazing lands, under correct management.

5837. Faging pasture lands is a practice which is sometimes adopted in districts where there is a scarcity of winter food. Under this system, fields in pastures, and open fields, are mown as rough as the state till November or December, when the farmer's stock is turned in, and continue to pasture till the May succeeding. Such management, however, can only be advisable on a soil of the driest nature, which will not become injured by pasturing in the wettest seasons. It is practised in a few places in Cardiganshire; but is considered by the late Thos. Johns, Esq., of Hafod, as the result of necessity in places where they were being able to bring sufficient stock to eat it down in season, when its nutritive powers are in their best state.

5838. Water should be provided for every field under pasture; and also shelter and shade, either by a few trees, or by a portable shed, which may be moved with the stock from one enclosure to another. Where there are no trees, rubbing posts are also found a desirable addition. In Germany they have portable sheds which are employed both in summer and winter, and generally with a piece of rock-salt fixed to a post for the cattle to snack at. (Fig. 796.)

SUBJECT. 2. Hilly and Mountainous Pastures.

5839. Hilly pastures include such low hills as produce fine short herbage, and are with much advantage kept constantly in pasture, though they are not altogether inaccessible to the plough; as well as such tracts as, from their activity and elevation, must necessarily be exclusively appropriated to live stock. The former description of grass lands, though different from the feeding pastures, of which we have just treated, in respect to their being less convenient for tillage management, are nevertheless in other circumstances so nearly similar, as not to require any separate discussion. These low hills are for the most part occupied with sheep, a very few cattle being sometimes pastured towards their bases; and they frequently comprise herbage sufficiently rich for fattening sheep, together with coarser pastures for breeding and rearing them.

5840. In regard to the management of upland pastures, of the rules which judicious farmers practise, the following deserve to be selected:—

5841. To enclose those pastures, as the same extent of land, when sheltered, and properly treated, will feed a greater quantity of stock, and to better purpose, than when in an open and exposed state. Not to overstock upland pastures; for when this is done, the cattle are not only starved, and the quantity of herbage diminished, but the soil is impoverished. When the pasture ground is enclosed and subdivided, so as to admit of it, the stock ought to be shifted from one enclosure to another, at proper intervals; giving the first of the grass to the fattening, in preference to the other stock. This practice tends to increase the quantity of grass, which has thus time to get up; and the ground being fresh and untainted, when the stock returns to it, more especially if rain has fallen, they will feed with greater appetite and relish. The dung dropped by the stock, while feeding, should be spread about, instead of being suffered to remain where it was deposited, in a solid body. Where the larger and the smaller kinds of stock are to be fed on the same pastures, the larger species should have the first bite; and it is not thought by some advisable to destapare land with a mixed collection of different species of live stock, unless the field is extensive, or unless the herbage varies in different parts of the field. It is generally found, that the grass produced by the dung of cattle or horses is injurious to sheep, producing grass of too rich a quality for that species of stock. There is no mode by which such pastures are more effectually improved, than by the application of lime, either spread upon the surface or mixed with the soil. In the latter case, it is essential that the lime should be mixed with the surface soil only; as lime is apt to sink, if covered deeply by the plough. The coarse grasses would, in that case, regain possession of the soil, and the dung afterwards deposited by the cattle will not enrich the land in the same manner as if the lime had been incorporated with the surface only. (Codic.)

5842. Mountainous pastures, from which the plough is altogether excluded, have been commonly classed among waste lands; even such of them as bear herbage by no means of inconsiderable value; as well as heaths and moors with patches of which the green pastures are often chequered. The general term wastes is therefore a very indefinite expression; and, indeed, is unfitly made to comprehend all that extensive division of our territory that neither produces corn nor rich herbage. Yet it is on such tracts that by far the greater part of our butcher's meat, and of our mutton, is grown, and not a little of the food, which, when there is still time to tender, is sold for market. Foreigners and superficial readers at home must accordingly be greatly mistaken, if they imagine that what are called wastes by the Board of Agriculture, and other writers on rural economy, are really altogether unproductive; and it would be a still grosser error to believe that all those wastes owe their continuance to neglect or mismanagement; and that any exertions of human industry can ever render the greater part of them, including all the mountainous tract of Great Britain, more valuable than they are at present, without a much greater
expenditure of capital than, under almost any circumstances, they could possibly return. (Sup. art. Agr.)

5843. Menteath of Closburn, in Dumfrieshire, has regenerated old pasture by paring up the turf with a powerful scythe or scythe-plow for a week or two, and then to have it thrashed with a flail or newfork, before the subsoil had been stirred by ploughing and harrowing, and a little lime, ashes, or other manure added. A field so treated was found, in four years, to keep fifteen head of cattle fully better than it did ten in its former state. The improvement is considered to give of annual profit one third of the prime cost, so that in little more than four years it will clear itself. (Gard. Mag. vol. vi.)

5844. Improving pasture without taking a crop of corn. The same gentleman having had a considerable extent of the poorest moorland in Scotland in his estate of Closburn, Dumfriesshire, entertained the opinion that the future improvement of these lands would result from taking the pasture off them, when, in general was a peat earth upon a gravel or sand or red freestone, and which he considered too poor to produce a remunerating crop of corn. He accordingly set to work to improve about a thousand acres of this extent of land. He first removed the turf, and sometimes pit one foot, and turned nearly two hundred acres in one summer, which he ploughed in the autumn and allowed to lie in that state till the next spring, when he laid on about one hundred and seventy bushels of quicklime, or lime shells, as they are there called from their shellings or falling to pieces when watered, per English acre, and in the month of July harrowed in between five and six bushels of Hectus flactus grass seed. The greatest part of this land has now been improved about twenty years, and is continuing to yield abundance of grass, and is worth from 12s. to 1£ per acre, while in its natural state it was scarcely worth 2s. 6d. per acre. He was so convinced it would pay amply for another dressing of lime, which a Scotch farmer, he says, would not think of, as the plough is upon all occasions the implement in most active operation with him. In the improvement of moor ground, Mr. M. thinks it highly important to state that the very worst effects result from pulverising or bringing the peaty or vegetable soil to a complete state of putrefaction or pulvuration, before being laid down to pasture; and that this must certainly take place when two or three corn crops are taken before sowing out. Moony peaty soil after this treatment is liable to be poisoned in wet weather, and in dry weather is almost equally incoherent, and is difficult to be again restored without dung or great quantities of earth. (C. G. Stuart Menteath, March 1832, in Gard. Mag. vol. vi.)

5845. The chief improvements of which mountainous pastures are susceptible are, draining and sheltering by scarifying or smoothing the uncultivated parts of them, and enclosing them with stone walls, or by stone walls alone; but as the stock on mountain pastures are generally under the care of a shepherd, the advantages of change of pasture and alternate eating down and saving or sparing the grass, by keeping out the cattle, are obtainable without the use of fields.

Sect. III. Improvement of Grass Lands, by a temporary Conversion to Tillage.

5846. The practice of breaking up grass lands, either with a view to their being soon after restored, or to their permanent retention in aration, has occasioned much discussion, and even attracted the attention of the Legislature, and the Board of Agriculture. In The Code of Agriculture it is stated, that a "much larger proportion of the united kingdom, than is at present so cultivated, might be subjected to the alternate system of husbandry, or transferred from grass to tillage, and then restored to grass." Much of the middling sorts of grass lands, from 200 to 400 feet above the level of the sea, is of this description; and many husbandmen, and most indiscriminate friends of the corn laws and the landed monopoly, regret that such lands are left in a state of unproductive pasture, and excluded from tillage. Were the trade in corn free, the idea of tilling such lands would be at least problematical.

5847. A very extensive enquiry was made, in consequence of a requisition from the House of Lords to the Board of Agriculture, in December 1800, "into the best means of converting certain portions of grass lands into tillage, without exhausting the soil, and of returning the same to grass, after a certain period, in an improved state, or at least without injury," and the information collected by the Board, upon that subject, has been the subject of the most important discussions.

5848. On this subject the opinion of one of our first writers is, "that though it is impossible to deny that much grass land in England would be more productive, both to the proprietor and occupier, under a good course of crop rotation, that it is no less certain, that there are large tracts of rich grazing land, which, in the present state of the demand for the produce of grass lands, and of the law of England, with regard to tithes, cannot be employed more profitably for the parties concerned, than in pasture. The interest which the Board of Agriculture has taken in this question, with a view to an abundant supply of corn, for the wants of a rapidly increasing population, seems, therefore, not to have been well directed. Instead of devoting a large portion of their valuations to the instruction of farmers, regarding the best method of bringing grass lands into tillage, and restoring them again to meadow or pasture, without neglecting the first thing required was, to attempt removing the almost insuperable obstruction of tithes, by proposing to the legislature an equitable plan of commutation. If some beneficial arrangement were adopted on this head, there is no reason to doubt, that individual interest would soon operate the wished-for change; and that all grass lands capable of yielding more rent and profit under tillage than under pasture would be subjected to the plough, as fast as the demands of the population might require. (Sup. E. B. art Agr.)

5849. In giving the essence of the information collected by the Board, we shall first state the opinions as to such grass lands as should not be broken up, and next the directions for breaking up and laying down the others.

Subsect. 1. Grass Lands that ought not to be broken up by the Plough.

5850. There are various sorts of grass lands that ought not to be broken up; as water meadows; salt marshes; lands apt to be overflowed; lands near large populous towns, where the produce of grass land is always in demand, and consequently dear; and low-lying tracts, in the valleys of mountainous countries, particularly in chalky districts, where old meadow land is scarce, and where a portion of it, to raise early and late food for stock, gives a great additional value to the adjoining upland. But whether rich lands, which have long remained in grass, and continue productive, should ever be converted into tillage, is a question respecting which a great diversity of opinion has been entertained.
5851. The lands considered as best adapted for permanent pasture are of three kinds: strong tenacious clays, unfit for turnips or barley, which are said to improve the more the longer they are kept under a judicious system in grass; soft clayey loams, with a clayey or marly bottom or substratum; and rich, sound, deep-soiled land, or vall land, enriched by nature at the expense of the higher grounds, generally lying in a situation favourable with respect to climate.

5852. The advantages of such pastures are represented in the strongest light. It is affirmed, that they feed cattle to a greater weight; that they are not so easily scorched by the summer's drought; that the grasses are more nutritive, both for sheep and cattle; that milch cows fed upon them give richer milk; and that beef cattle and cheese are that the heads of all animals pastured on them are much better preserved; that they produce a greater variety of grasses; that, when properly laid down, they yield a succession of pasture throughout the whole season; that the herbage is sweeter, and more easily digested; and that the returns are immense, producing a trifling expense.

5853. To break up lands possessing these advantages, it is said, can only be justified by the most urgent public necessity, and to prevent the horrors of famine. The real value of such lands will appear by considering their rent and produce. The best grass lands in Lincolnshire and Lincolnshire, adapted to grass, amongst others, are various, from 1.15s. to 3l. per acre; and the value of the produce from 3l. per acre to 10l. This produce arises from beef, mutton, and wool; and is obtained subject to little variation from the nature of the seasons, and at a trifling expense. The stock maintains per acre on the best grazing lands six to seven sheep in summer, and about two sheep in winter. The sheep, when put on the grass, may weigh from 18 lbs. to 20 lbs. per quarter, and the increase of weight would be at the rate of 4 lbs. per quarter, or 16lbs. per sheep. But suppose in all only 100 lbs. at 8d. per pound, that would amount to 1l. 4s. The wool would be worth about two guineas more, besides the value of the winter keep; and the total may be stated at about 7l. per acre, got at little expense. Such lands, it is evident, cannot be better employed than in feeding stock.

5854. Grass land on tenacious clays and heavy loams, when brought in a succession of years, or perhaps of ages, into a state of great productiveness, cannot be ploughed without the risk of great injury, and are more profitable in the production of herbage than they could be in the production of grain.

5855. Grass on deep-soiled sound vall lands would be productive of corn if ploughed; but would be probably injured by cultivation: from their texture being altered, and rendered unyieldy loose and open by tillage; from the native plants being more or less destroyed or enfeebled; and from the great decomposition and waste of the principles of fertility resident in the soil.

5856. The extent of these descriptions of land, however, is not so great that the advantages of breaking them up could probably ever be a national object, or worth the risk of injuring their future productiveness in grass. But there are pasture lands of an inferior sort, which are too apt to be confounded with those already described; and respecting the propriety of occasionally appropriating them to arable culture, there can hardly be a doubt. Such lands do not depend upon their intrinsic fertility, but upon annual supplies of manure derived from the arable land in their neighbourhood.

SUBSECT. 2. Advantages and Disadvantages of breaking up Grass Lands.

5857. The advantages of breaking up grass lands, not of the richest quality, will appear by a comparison of their produce with that of arable lands.

5858. From the enquiry of the Board of Agriculture, it appears that an acre of clover, tares, rape, potatoes, turnips, cole, or cabbages, will furnish at least three times as much food as the same acre would have done, had it remained in pasture of a medium quality; and, consequently, that the same extent of land would maintain at least as much stock when in grass, besides producing every other year a valuable crop of corn; at which time, whatever is left, which, after the expense of manure, would add considerably to the stock of manure. This follows, that, with the exception of rich pastures, arable land is, on an average, superior to grass land, with respect to furnishing articles of human food, in the proportion of three to one; and consequently every piece of grass unnecessarily kept in grass, the produce of which will only maintain one person, is depriving the community of food capable of maintaining two additional members.

5859. The principal objection to the conversion of old turf into arable land arises from an alleged inferiority, both in bulk and nutritive properties, in the new when compared to the old herbage. It is certain, that by no art can we at once produce a surface of grasses which can be at all compared to some of the richest pastures in Buckinghamshire, Lincolnshire, and Leicester; but these are not the pastures which the prudent agriculturist would recommend to him, in which the system of permanent pasture should be carried on, and which must ultimately be converted into arable land; but those which, by the admission of all, are less productive, and which, perhaps, will add considerably to the stock of manure. Still, in by far the greater number of cases where the soil will admit of the convertible husbandry, and where that husbandry is as well understood and practised as it is in the north of England and south of Scotland, we should have no hesitation in leaving it to the farmer to break up whatever pastures he thought he could do with profit during a fourteen or twenty-one years' lease. A gentleman who had a large farm, principally consisting of strong rich clay every field of which, with hardly any exception, he occasionally broke up, was accustomed to lay them down with a crop of barley, and to sow fourteen pounds of white clover, a peck of rib-grass, and three quarters of hay seeds, per acre. By this liberal allowance of seed, he always secured a thick cover of herbage the first year, which differed from old pasture in no respect. Such land, under tender management, will not be injured by the plough. When laid down from tillage into grass, they may not carry for the first year or two such heavy cattle as they would afterwards; but they will support more in number, though of a smaller size, and bring a greater weight of butcher meat to market. It is often desirable to keep one or two moderate-sized herds, consisting of from ten to twenty acres, according to the size of the farm, in permanent pasture, for the feeding of cattle and sheep, and as a resource for the stock to go to in case of a severe spring or summer drought; but the retaining of any considerable portion of a farm in old turf, or permanent pasture, unless of the richest quality, is in general injurious to the landlord, the tenant, and the public. The value of every farm, and the profit of any estate, where the system of permanent pasture has been carried to an unreasonable extent, may be easily and greatly augmented by appropriating the manure of the farm to turnips and other green crops, and by the adoption of the convertible system of husbandry.14
5863. If the land be wet, it is advisable to drain it completely, previously to its being broken up; for it is not improbable that its being kept in pasture was partly on account of its wetness.

5864. Wherever the soil is not too shallow, nor of a friable nature, or when the turf cannot soon be rotted, if land is to be broken up from old pasture, the system of paring and burning is proper. In this way, good tilth is speedily procured; the damage that might otherwise be sustained by the grub, the wire-worm, and other insects, is avoided, while the soil receives a stimulus which ensures an abundant crop.

5865. The rotation of crops to be adopted, when grass lands are broken up, must partly depend upon the soil, and partly on the manner in which it is prepared for cultivation. As a general principle, however, it may be laid down, that unless by the course of cropping to be pursued the bad grasses and other plants indigenous to the soil are extirpated, they will, when the land is again laid down to grass, increase and prevail with more rapidity and effect than seeds chosen by the farmer; and the consequence must be, a great disappointment in the future crops of grass, perhaps solely, or at least principally, attributable to a previous defective management. It is necessary, therefore, to enter into details upon this subject as applicable to clay, chalk, peat, loam, and sand.

5866. Clay. The process of conversion in clayey soils should be commenced with paring and burning, especially where the grub is suspected. The following course may then be adopted:—1. Rape, fed with straw; 2. barley; 3. follow; 4. beans; 5. wheat; 6. wheat, sown with grass seeds, only everal; both furrows not exceeding the thickness of the vegetable mould or other good soil. If the land be ploughed with one furrow, the operation ought to be performed before winter, that it may receive the benefit of the succeeding frosts, by which the success of the future operations will not only be promoted, but most of the insects bred in the soil will be destroyed. When one furrow alone is taken, the best size is four inches and a half deep by eight or nine broad. The strain on horses in ploughing ley land is most from the depth.

5867. The process of conversion in clayey soils should be commenced with paring and burning, especially where the grub is suspected. The following course may then be adopted:—1. Rape, fed with straw; 2. barley; 3. follow; 4. beans; 5. wheat; 6. wheat, sown with grass seeds, only everal; both furrows not exceeding the thickness of the vegetable mould or other good soil. If the land be ploughed with one furrow, the operation ought to be performed before winter, that it may receive the benefit of the succeeding frosts, by which the success of the future operations will not only be promoted, but most of the insects bred in the soil will be destroyed. When one furrow alone is taken, the best size is four inches and a half deep by eight or nine broad. The strain on horses in ploughing ley land is most from the depth.
of lime, where it can be obtained, is of the greatest service in enabling such soils to bring corn to its full perfection. In the few of Norther, the following course was recommended:—1. Vear and burning for rape; 2. oats; and 3. wheat with grass-seeds; if the land was safe from water, the Lammars sort, if not, spring wheat. This short course, it is contended, preserves the land in heart; and it afterwards produces abundant crops of grass. But long courses, in such a soil, run the lands to weeds and straw, without quality in the grain.

5871. Loam. The courses of crops applicable to this soil are too numerous to be here inserted. If the sward is fragile, the following rotation may be adopted:—1. Oats; 2. turnips; 3. wheat or barley; 4. fallow or turnips; 5. barley; 6. wheat or barley; 7. wheat or barley; 8. grass-seeds. If the sward is very tough and coarse, instead of taking oats, it may be parcel and burnt for turnips

5872. Sand. On rich and deep sandy soils, the most valuable that can be raised is a crop of carrots. For inferior sands, turnips, to be eaten on the ground; which should then be laid down with barley and grass-seeds.

5873. According to the improved system of laying down lands to grass, land ought to be previously made as clean and fertile as possible. With that view, all the green crops raised ought to be consumed upon the ground; fallow or fallow crops ought not to be neglected; and the whole straw of the corn crops should be converted into manure, and applied to the soil that produced it. Above all, the mixing of calcareous matter with the soil, either previously to, or during the course of, cropping, is essential. Nothing generally improves meadows or pastures more than lime or marl: they sweeten the herbage, render it more palatable to stock, and give it more nourishing properties.

5874. When turnips are raised upon light land, sheep should be folded on them; whereas, if the land is strong or wet, the crop should be drawn, and fed in some adjoining grass-field, or in sheds. If the land is in high condition, it is customary to cut off half the turnips, and eat the other on the ground. But this is not a plan to be recommended on poor soils.

5875. It has been disputed whether grass-seeds should be sown with or without corn. In favour of the first practice, that of sowing the two crops, it is maintained, that where equal pains are taken, the future crop of grass will succeed as well as if they had been sown separately, while the whole tithes answer for both. On the other hand, it is observed, that as the land must, in that case, be put into the best possible order, there is a risk that the corn-crop will grow so luxuriantly as to overpower the grass-seeds, and, at any rate, will exclude them from the benefit of the air and the dew. If the season also be wet, a corn crop is apt to lodge, and the grass will, in a great measure, be destroyed. On soils moderately fertile, the grasses have a better chance of succeeding; but then, it is said, that the land is so much exhausted by producing the corn-crops, that it seldom proves good grass land afterwards. In answer to these objections, it has been urged, that where, from the richness of the soil, there is any risk of sowing a full crop of corn, less seed is used, even as low as one third of the usual quantity; and that a moderate crop of grain nurses the young plants of grass, and protects them from the rays of a hot sun, without producing any material injury.

Where the two crops are united, barley is the preferable grain, except on peat. Barley has a tendency to loosen the texture of the ground in which it grows, which is favourable to the vegetation of grass-seeds. In the choice of barley, that sort should be preferred which runs least to straw, and which is the sooner ripe. On good peat, a crop of barley is to be preferred. The most recent practice of the best farmers is in favour of sowing the grass-seeds without the addition of corn, or any other temporary plant.

5876. The manner of sowing the grass-seeds also requires to be particularly attended to. Machines have been invented for that purpose, which answer well, but they are unfortunately too expensive for the generality of farmers. It is a bad system, to mix seeds of different plants before sowing them, in order to have the fewer casts. It is better, to sow each sort separately; for the expense of going several times over the ground is nothing, compared to the benefit of having each sort equally distributed. The seeds of grasses being so light, ought never to be sown in a windy day, except by machinery, an equal delivery being a point of great consequence. Wet weather ought likewise to be avoided, as the least degree of poaching is injurious. Grass seeds ought to be well barrowed, according to the nature of the soil.

5877. When the corn is carried off, the young crop of grass should be but little fed during autumn, and that only in dry weather; but heavily rolled in the following spring, in order to press the soil home to the roots. It is then to be treated as permanent pasture. By attention to these particulars, the far greater proportion of the meadows and pastures in the kingdom, of an inferior, or even medium quality, may be broken up, not only with safety, but with great profit to all concerned.

Chap. VIII.

Plants cultivated on a limited Scale for various Arts and Manufactures.

5878. The plants used as food for men and animals are by far the most generally cultivated in every country; and, next, those of clothing, building, and other arts of convenience or luxury. The former are often called agricultural, and the latter commercial or manufactorial plants. Of manufactorial plants, only a few are at present cultivated in Britain; the national policy rendering it preferable to import them, or substitute, from other countries. Some, however, are still grown in nearly sufficient quantities for home consumption, as the hop, mustard, rape, and a considerable quantity of flax, anise, and caraway; some hemp, teasel, and wood are also raised. These and other plants may be classed as grown for the clothing, distilling, brewing, oil-making, and domestic and medical arts.

Sect. I. Plants grown chiefly for the Clothing Arts.

5879. The clothing plants are flax, hemp, teasel, madder, wood, and weld; the first three are used by the manufacturer of the fabric, and the others by the dyer.
Subsect. 1. Flax. — *Linum usitatissimum* L.; *Pentandra Pentagonia* L., and *Linum* (Tr.); *Flacks*, Ger.; and *Lino*, Ital. and Span. (fig. 797. 6.)

5880. *The flax* has been cultivated from the earliest ages, and for an unknown length of time in Britain, of which it is now considered a naturalised inhabitant. It is cultivated both for its fibre for making thread, and its seed for being crushed for oil; but never has been grown in sufficient quantity for either purpose. The legislature of the country, as Brown observes, has paid more attention to framing laws regarding the husbandry of flax than to any other branch of rural economy; but it need not excite surprise that these laws, even though accompanied by premiums, have failed to induce men to act in a manner contrary to their own interest. The fact is, the culture of flax is found on the whole less profitable than the culture of corn. It is one of the most severe crops when allowed to ripen its seed; but by no means so when pulled green.

5881. *The varieties of the common flax* are few, and scarcely deserving of notice. Marshal mentions the blue or lead-coloured flax as being cultivated in Yorkshire, and Professor Thaer mentions a finer and coarser variety; he also, as well as some other agriculturists, has tried the *Linum perenne* (b), but though it affords a strong fibre, it is coarse and difficult to separate from the woody matter.

5882. *The soils* most proper for flax, besides the alluvial kinds, are deep and friable loams, and such as contain a large proportion of vegetable matter in their composition. Strong clays do not answer well, nor soils of a gravelly or dry sandy nature. But whatever is the kind of soil, it ought neither to be in too poor nor in too rich a condition: because, in the latter case, the flax is apt to grow too luxuriantly, and to produce a coarse sort; and, in the former case, the plant, from growing weakly, affords only a small produce. (Tr. on Rural Affairs.)

5883. *If there is water at a small depth below the surface of the ground*, it is thought by some still better; as in Zealand, which is remarkable for the fineness of its flax, and where the soil is deep and rather stiff, with water almost every where, at the depth of a foot and a half or two feet. It is said to be owing to the want of this advantage, that the other provinces of Holland do not succeed equally well in the culture of this useful plant; not that fine flax is also raised on high lands, if they have been well tilled and manured, and if the seasons are not very dry. It is remarked, in the letters of the Dublin Agricultural Society, that most stiff soils yield much larger quantities of flax, and far better seed, than can be obtained from light lands; and that the seed secured from the former may, with proper care, be rendered full as good as any that is imported from Riga or Zealand. M. Du Hamel, however, thinks that strong land can hardly yield such fine flax as lighter ground.

5884. *The place of flax in a rotation of crops* is various, but in general it is considered as a corn or exhausting crop, when the seed is allowed to ripen; and as a green, or pea, or bean crop, when the plant is pulled green.

5885. *Flax, Donaldson observes, is sown after all sorts of crops, but is found to succeed best on lands lately broken up from grass*. In Scotland, the most skilful cultivators of flax generally prefer lands from which one crop of grain only has been taken, after having been several years in pasture. When such lands have been limed or marled, immediately before being laid down to grass, the crop of flax seldom or never misgives, unless the season prove remarkably adverse. In the north of Ireland flax is generally sown by the small farmers after potatoes. In Belgium, it is supposed not to do well after peas or beans; nor to succeed if sown oftener on the same soil than twice in nine years. (Von Thaer.)

5886. *The preparation of the soil*, when grass land is intended for flax, consists in breaking it up as early in the season as possible, so that the soil may be duly mollified by the winter frosts, and in good order for being reduced by the harrows, when the seed process is attempted. If flax is to succeed a corn crop, the like care is required, to procure the aid of frost, without which the surface cannot be rendered fine enough for receiving the seed. Less frost, however, will do in the latter than in the former case, therefore, the grass land ought always to be earliest ploughed. At seed-time, harrow the land well before the seed is distributed, then cover the seed to a sufficient depth, by giving a close double harrowing with the harrows. Water-furrow the land, and remove any stones and roots that may remain on the surface, which finishes the seed process.

5887. *The ordinary season of sowing flax-seed* is from the middle of March to the middle or end of April, but the last week of March and the first ten days of April are esteemed the best time; and accordingly within these periods the greatest quantity of flax-seed is sown in this country. In France and Italy it is often sown in the autumn, by which a larger crop is produced, especially when seed is desired.

5888. *The quantity of seed* depends on the intention of the crop. When a crop of seed is intended to be taken, thin sowing is preferable, in order that the plants may have room to throw out lateral shoots, and to obtain air in the blossoming and filling seasons.
But it is a mistake to sow thin when flax is intended to be taken; for the crop then becomes coarse, and often unproductive. From eight to ten pecks per acre is the proper quantity in the last case, but when seed is the object, six pecks will do very well. (Brown.) Thick-sown flax runs up in height, and produces fine soft flax; if sown thin, it does not rise so high, but spreads more and puts forth many side branches, which produce abundance of seed, and such seed is much better filled, plumper and heavier, than the seed produced from thick-sown flax. (Donaldson.)

5889. In the choice of seed, which is of a bright brownish colour, only to the feel, and at the same time weighty, is considered the best. 5890. Linseed, imported from various countries, is employed. That brought from Holland is, however, in the highest estimation; as it not only ripens sooner than any other, but is less subject to the blights and other calamities of the country. American seed produces, in common, fine flax; but neither the quantity of flax nor of the pods, provincially the "hulls," which contain the seeds, is so large as the produce from Dutch linseed. Inga seed yields a very coarse sort of flax, but a greater quantity of seeds than any other. It is common in some parts of Scotland. The success of this practice is found to depend greatly on changing the seed from one sort of soil to another of an opposite nature; so that the expense of in this way is newly imported from Holland, is so considerable, and the risk of the crop misgiving so much greater in the one case than in the other, that only those who are ignorant of the consequences, or who are compelled from necessity, are chargeable with this act of ill-considered simony. Flax seed is by some farmers changed every three years, but many have sown the same seed ten years in succession, without perceiving any degeneracy. When any degeneracy takes place, the seed of flax grown on a different soil, as moss, moor, sand, &c., without any view to the produce in flax, will, it is said, answer as well as foreign seed.

5891. The manner of sowing is almost always the same; but when seed is the main object, drilling may be adopted, by which seed will be saved in sowing, cleaning conducted at less expense, and the plants rendered more vigorous and branchy by the stirring of the soil and the admission of air between the rows. The fibres of flax grown in this way, however, will be shorter, and less equal in thickness throughout their length, than flax grown by the broad-cast mode, and tolerably thick.

5892. The after-culture of flax consists chiefly in weeding, but sometimes it commences with rolling the surface, which is a very proper operation when the soil is very dry, the season advanced, or the earth very porous. By this process the earth is pressed firmly to the seeds, and they are thereby stimulated to vegetate sooner, and the drought is kept out. On some soils, and in wet or stormy seasons, flax is apt to be laid, to guard against which some cultivators run across their flax field slender poles fixed to stakes: but a better method is to run small ropes across the field, both lengthwise and breadthwise, where necessary; for these being fastened where they intersect one another, and supported by stakes at due distances, form a kind of network, which is proof against almost every accident that can happen from tempestuous weather.

5893. In Scotland a crop of flax, it is said, has been sometimes weeded by turning a flock of sheep at large into the field. They will not taste the young flax plants, but they carefully search for the seeds, which they devour.

5894. The flax crop is taken by pulling, on which there is a considerable difference of opinion. None, however, think of pulling it before it comes into flower, when fibre is the sole object; or before the seed in the capsules acquires a brownish colour, when fibre and seed jointly are required, or when seed alone is the object.

5895. Some argue for it pulling white green, in order that its fibres may be softer and finer; others, with the same view, pull it up before its seeds are quite formed; and others again think that it should not be pulled till some of the capsules which contain the seeds have begun to open, being of opinion that the fibres of green flax are too tender, and that they fall into to pieces. On the whole hand, it is certain the fibres of flax which has stood till it is very ripe are always stiff and harsh, that they are not easily separated from the seed, and that they do not bleach well. Here, therefore, as in most other cases, both extremes should be avoided; and what seems most reasonable to think that the proper time for pulling flax, is when its stalks begins to turn from a green to a yellow, when its leaves begin to fall, and when its seeds begin to be brown. Donaldson observes, that a crop of flax frequently grows short, and runs out a great number of seed-bearing branches. When that is the case, the whole, or a part of the farmyard be be sowed to turn, till the seeds are in a great measure perfected. But that when the crop thrives, and is likely to become more valuable for the flax than the seeds, it should be pulled soon after the bloom drops off, and before the pods turn hard and sharp in the points. When allowed to take its full time, it considers it a little early, any thing wanting in quantity being, in this way, made up by the superiority of quality.

5896. The operation of pulling flax differs according to the intention of the crop. When it is grown for the field, it is put in a tined cart, and placed like a bundle to be accommodated to the wall. But when the seed is to be taken from the plant, it is pulled and laid in handfulls.

5897. In pulling flax, it is usual, when it is intended to save the seeds, to lay it in handfuls, partly across each other; the reason of this is, the business of pulling is thereby facilitated, as the rapiers, in place of having to separate each handful from the bundle, bind it by this simple precaution already proposed to the case. Although it is much inconsiderable, yet it very seldom happens that much attention is bestowed on that part of the business, and the careful separation of each other in pulling the crop. In most fields, there are varieties of soil, and different parts of a field furnish fine flax, others coarse; some long, and some short: in a word, crops of different lengths and qualities of flax, which are of the same sort, are to be distinguished. These sorts of flax all undergo an equal degree of watering, grassing, breaking, and heckling, without sustaining great injury.

5898. As the flax is pulled, it is laid together by handfuls, with the seed turned to the mouth. These handfuls should neither lie quite in line with each other, nor directly across, but a little slanting upwards, so that the air may easily pass through them. None, instead of this method, tie the handfuls of flax loosely at the top, then spread out the roots, and thus set several of them together upright upon their roots. In either of these cases, the flax is air, by which its fibres are dried in the field to dry it. This drying is certainly not necessary for the fibre; but then the air will separate the capsules from the flax so effectually before it has been dried as it will afterwards, after the flax has been dried out. On a fine dry seed, it should be considered, that the flax will be more hurt by the latter method of drying; for the longer it is kept, the more it is exposed to the influence of this drying; the seed can be better dried by the air, but the more the moist urinary which connects the fibres in the seed is dried, it shall be the greater the degree of saturation necessary to loosen and destroy the cohesion of this connecting membrane; the finer parts of the flax itself most necessarily be
5899. In the process of rippling, which is the next operation, a large cloth should be spread on a convenient spot of ground, with the ripple placed in the middle of it.

5900. In performing this business, the pods containing the seeds are forced from the stalks by means of the iron comb called a ripple, fixed on a beam of wood, on the ends of which two persons sit, who, by pulling opposite to one another, raise the comb through the ripples in a regular manner.

It is remarked by the author of The Present State of Husbandry in Great Britain, that "those who bestow much attention on the cultivation of flax in Scotland generally ripple the seed, even when there is little or no putrefaction; when flax is put into water without taking off the pods, the water soon becomes putrid, in consequence of which the flax is greatly injured."

5901. The management of the capsules, and the separation of the seed, form the next operation.

5902. The capsules obtained should be spread in the sun to dry, and those which separate from the pods of the plant, after having been tied in bales, should be set apart for sawing, in case the precaution of raising some flax purposely for seed has not been attended to. The capsules are then broken, either by treading or by threshing, in order to get out the remaining seeds, the whole of which, as well as the others, should be carefully sifted, winnowed, and cleaned. When the seed is well cured, it will be found, when the weight placed above may keep the whole firmly down. The weights made use of are commonly stones placed on planks, or directly on the flax.

5904. Bleaching is a tedious and laborious operation when it is intended as a substitute for steeping, but it is very advantageously adopted on a large scale when steeping places are not at hand. In Dorsetshire, and some other places, flax, instead of being steeped, is what is called dew-retted; that is, the stalks are allowed to stand at that state in which the harl or woody parts separate most easily from the boon, reed, or fibre, by a more gradual process of retting by dry means and interposition of a warm day. This is than exposed to the climate and to the influence of the weather for a longer period than is necessary, when the operation of watering has been previously performed. Steeping, however, is the most universal practice both in Britain and on the Continent.

5905. Steeping may be regarded as the general practice till flax-dressing machines come into universal use. In performing this operation, the flax, whether it has been dried and rippled, or pulled green, is loosely tied into small bundles, the smaller the better, for it is then most equally watered; and these bundles are built up in the pool in a reclining upright posture, so that the weight placed above may keep them firmly held down. The weights made use of are commonly stones placed on planks, or directly on the flax.

5906. The Flemish mode of steeping flax, as described by Radcliff, is to improve the quality of the flax. This mode differs from the common practice, in placing the bundles in the steep vertically, instead of horizontally; in immersing the flax by means of transverse sticks, with that degree of weight annexed which shall not push it down to the bottom, but leave it to the power to descend spontaneously, until the conclusion of the steepage; and in leaving at first a space of at least half a foot between the bottom and the roots of the flax. The spontaneous descent of the flax is an indication of its being sufficiently steeped; and the strength and quality of the fibre are said to be much better preserved by this mode, in which the temperature of the atmosphere acts with most force on the upper part of the plant, which needs it most.

5907. The water most proper for steeping flax should be clear, soft, and in standing pools. Compared with running water, pools occasion the flax to have a better colour, to be sooner ready for the grass, and even to be of superior quality, when dry. When soft, clear, stagnating water cannot be obtained, when the pool or canal is commonly formed, adjoining to a river or stream, whence water can be easily brought. This pit or canal is filled with water for some time (a week or two) before it is proposed to pull the flax; by this means the water acquires a greater degree of warmth than river-water possesses, which comes down cold. They who have seen green flax before it is boiled, have seen it in water, namely, to make the harl or flaxy substance part easily and completely from the boon or reed.

5908. The period that flax ought to remain in the water, depends on various circumstances; as the state of ripening, which is generally expressed by the ripeness of the pods, the quality and temperature of the water, &c. The most certain rule by which to judge when flax is sufficiently watered is, when the boon becomes brittle, and the harl separates easily from it. In warm weather, ten days of the watering process are sufficient; but it is proper to examine the pods regularly after the seventh day, lest the flax should putrefy or rot, which sometimes happens in very warm weather. Twelve days will answer in any sort of weather; though it may be remarked, that it is better to give too little of the water, than too much, as any deficiency may be easily made up by suffering it to lie longer on the grass, whereas an excess of water admits of no remedy.

5909. Grassing or bleaching flax is the next operation, the intention of which is to rectify any defect in the watering process, and carry on the putrefactive process to that point when the fibre will separate from the bark, boon, reed, or harl (as the woody part of the stem is called), with the greatest ease. In performing this operation, the flax is spread on the ground, and in regular rows; the one being made to overlap the other a few inches, with a view of preventing, as much as possible, its being torn up and scattered by gales of wind. Old grass-ground, where the herbage does not grow to any great height, is the best for the purpose; as when the flax is covered by the grass or weeds, it is frequently rotten, or at least greatly injured thereby.

5910. The time allowed for grassing is regulated by the state of the flax, and seldom exceeds ten or twelve days. During this time it is repeatedly examined, and when it is found that the boon has become very friable, and that, on bending between the heads, it easily and freely parts from the harl, it is taken up, a dry day being chosen for the purpose, and, being bound in sheaves, is either sent direct to the mill, which is the usual practice in the northern districts, or broken and scutched by a machine for or implement for the purpose.

5911. Steeping flax in hot water and soft soap (said to be the invention of Lee, and for which he was granted by parliament a secret or unenrolled patent) is said to separate the fibre from the woody matter better than steeping in water only, and this in the short space of two or three hours. But even this green flax, or as much as has been dried and stacked for months or years, when flax is to be separated by this new mode, the cultivator has only to pull it in handfuls, dry it, bind it into sheaves or faggots, and put it up in stacks like corn, till wanted by the manufacturer.

5912. The dressing of flax consists of various operations, such as scutching, tracking,
or breaking, by which the woody part is broken; and heckling or combing, by which the fibre is separated from the woody part, and sorted into lengths. These operations are often all performed by the cotter, or small farmer, who grows flax for the purpose of spinning the fibre in his own family. But there are also public flax mills, impelled by water or other powers, by which flax is scutched, and it is then heckled by professed hecklers.

5913. A method of preparing flax in such a manner as to resemble cotton in whiteness and softness, as well as in coarseness, is given in The Swedish Transactions for the year 1747. For this purpose a little sea-water is to be put into an iron pot or an untinned copper kettle, and a mixture of equal parts of birch-ashes and quicklime strewn upon it; a small bundle of flax is to be opened and spread upon the surface, and covered with more of the mixture, and the stratification continued till the vessel is sufficiently filled. The whole is then to be boiled with sea-water for ten hours, fresh quantities of water being occasionally supplied in proportion to the evaporation, that the matter may never become dry. The boiled flax is to be immediately washed in the sea by a little at a time, in a basket, with a smooth stick at first, while hot; and when grown cold enough to be borne by the hands, it must be well rubbed, washed with soap, laid to bleach, and turned and watered every day. Repetitions of the washing with soap expedite the bleaching; after which the flax is to be beat, and again well washed; when dry, it is to be worked and carded in the same manner as cotton, and pressed between two boards for forty-eight hours. It is now fully prepared and fit for use. It loses in this process nearly half its weight, which, however, is abundantly compensated by the improvement made in its quality.

5914. Lee's method of breaking flax and hemp, without dew-retting, was invented in 1810, and was the first step towards a great improvement, brought nearer perfection by the new patent machines of Messrs. Hill and Bundy.

5915. Hill and Bundy's machines (fig. 789.) are portable, and may be worked in barns of any kind of house; they are also well calculated for parish workhouses and charitable institutions; a great part of the work being so light that it may be done by children and infirm persons; and such is the construction and simplicity of the machines, that no previous instruction or practice is required; their introduction, therefore, into these asylums would be the means of effecting a considerable reduction of the poor's rate. The woody part is removed by a very simple machine; and, by passing through a machine equally simple, the flax may be brought to a degree of fineness, equal to the best used in France and the Netherlands, for the finest lace and cambric. The original length of the fibre, as well as its strength, remains unimpaired; and the difference of the produce is immense, being nearly two thirds; one ton of flax being produced from four tons of stem. The expense of working each ton obtained by this method is only five pounds. The glutinous matter may be removed by soap and water only, which will bring the flax to such perfect whiteness, that no further cleaning is necessary, even after the linen is woven; and the whole process of preparing flax may be completed in six days.

5916. The produce of flax in seed is generally from six to eight, sometimes as high as ten or twelve, bushels per acre; and the price depends in a great measure on that of foreign seed imported; as, when sold to oil-makers, it is generally about one half of that of Dutch seed sold for the purpose of sowing.

5917. The price of home-cultivated flaxseed is considerably advanced of late in some of the southern and western counties of the kingdom, in proportion to what it is in the northern, owing to the circumstance of its being much used as food for fattening cattle. The average price of the linseed curried to the kingdom at large cannot, it is supposed, be rated higher than from three to four shillings the bushel. The seed is separated into three qualities; the best for sowing, the second best for crushing for oil, and the inferior for boiling or steaming for cattle.

5918. The produce of flax in fibre varies exceedingly. Before being sorted, the gross product of fibre varies from three cwt. to half a ton per acre.

5919. The use of flax in the linen manufacture is well known. The seed is crushed, or oil, which is that in common use by painters; the cake or husk, which remains after the expression of the oil, is sold for fattening cattle, and in some places as a manure; and the inferior seed, not fit to crush, is boiled and made into flaxseed jelly, which is esteemed excellent nutriment for stock.

5920. As the making of flaxseed jelly is an agricultural operation, we shall here describe it. The proportion of water to seed is about seven to one. The seed having been steeped in part of the water for eight and forty hours previously to the boiling; the remainder of the water is added cold, and the whole boiled gently about two hours, being kept in motion during the operation, to prevent its burning to the boiler. Thus the whole is reduced to a jelly-like, or rather a cream-like, consitency. After being cooled in tuns, it is given, with a mixture of barley-meal, bran, and cut chatt; a bullock being allowed about two quarters of the jelly per day, or somewhat more than one quart of seed in four days: that is, about one sixteenth of the medium allowance of oil-cake.

5921. The diseases of flax are few, and are chiefly the fly, which sometimes attacks the plants when young, the midge, and the rust.

5922. *The hemp* is a plant of equal antiquity with the flax. It is supposed to be a native of India, or of some other Asiatic country, being too tender to be even naturalised in Europe. It is one of the few plants employed in British agriculture in which the male and female flowers are in different plants, a circumstance which has some influence on its culture and management. It grows to a height great on good soils; sometimes to six or seven feet in this country, but in Italy generally higher; and Crud states, that in the Bolognese territory he has seen it fifteen feet eight inches high, and a friend of his eighteen feet six inches: in both cases the fibre being of remarkable beauty. This luxuriance of the hemp in warm countries may be one reason why it has never been much cultivated in England. In the Isle of Axholme, in Lincolnshire, it has been cultivated from time immemorial, and also for some centuries in Suffolk, but chiefly for local manufacture. The culture, management, and uses of hemp are nearly the same as those of flax. When grown for the seed, it is a very exhausting crop; but when pulled green, it is considered a cleaner of the ground, and is said to have the property of preserving from insects any crop which it may surround. The objections to this crop are, that its coming in the midst of harvest is embarrass-ing; and that the attention it demands in every state of its progress is too great, where it is only a secondary consideration.

5923. The soils most suitable for hemp are those of the deep black putrid vegetable kind, which have a situation low and somewhat inclined to moisture, as well as the deep mellow loamy or sandy sorts. But the quantity of produce is in general much greater on the former than the latter; though, according to some, of an inferior quality. Mellow rich clayey loams do well; and nothing better than old meadow land.

5924. The preparation of the soil, and the place in the rotation, are the same as for flax.

5925. The season of sowing is towards the end of April, when there is no longer any danger of frost injuring the rising plants. The quantity of seed is from two to three bushels, according to the quality of the land. In quality the seed must be fresh, heavy, and bright in colour. Broad-cast is the universal mode of sowing; and the only after-culture consists in keeping off birds when it is coming up; in weeding; and sometimes in supporting the crop by cross rods or lines, as in the case of flax.

5926. In taking the hemp crop, two methods are in use, according to the object in view. When the crop is grown entirely for the fibre, it is pulled when in flower, and no distinction made between the male and female plants. But as it is most commonly grown both with a view to fibre and seed, the usual practice is to pull the male plants as soon as the setting of the seed in the females shows that they have effected their purpose. As the female plants require four or five weeks to ripen their seeds, the males are thus pulled so long before them.

5927. In the operation of pulling the males, the pullers walk in the furrows between the ridges, and reach across the top of the ridge, pulling one or two stalks at a time, and carefully avoiding to tread down the female plants. The male stalks are easily known by their yellowish hue and faded flowers. They are tied in small bundles, and immediately carried to the watering pool, in the manner of flax.

5928. The operation of pulling the females commences when the seeds are ripe, which is known by the brownish or greyish hue of the capsules and the fading of the leaves. The stalks are then pulled and bound up into bundles, being set up in the same manner as grain, until the seed becomes so dry and firm as to shed freely; great care should be taken in pulling not to shake the stalks rashly, otherwise much of the seed will be lost. It is advised that, after pulling the seed, hemp may be set to stand in shocks of five to six sheaves, to dry the seed; but, in order to prevent any delay in watering, the seed-pods may be cut off with a chopping-knife, and dried on canvas exposed to the air under some shed or cover. This last method of drying the seed will prove of great advantage to the hemp, as the seed and pods, when green, are of such a gummy nature that the stings might suffer much by sun-burning or rain, which will discolor and injure the hemp before the seed can be sufficiently dried upon the stalks. Besides, the threshing out the seed would damage the hemp in a considerable degree.

5929. Hemp is watered (provin. water-retted), bleached (provin. dew-retted), and grassed in the same manner as flax. Grassing is omitted in some places, and drying substituted; and in other districts watering is omitted with the female crop, which is dried and stacked, and dewed or bleached the following spring. On the Continent hot water and green soap have been tried; and here, as in the case of flax, it is found that steeping for two hours in this mixture is as effectual in separating the fibre from the woody matter, as watering and grassing for weeks.

5930. Although hemp, in the process of manufacturing, passes through the hands of the breaker, heckler, spinner, whitener, weaver, and bleacher; yet many of these operations are frequently carried on by the same person. Some weavers bleach their own yarn and cloth; others their cloth only: some heckle their tow, and put it out to spinning; others buy the tow, and put it out; and some carry on the whole of the trade themselves.

5931. The produce of hemp in fibre varies from three to six cwt. per acre; in seed from eleven to twelve bushels.

5932. The uses of hemp are well known, as well as its great importance to the navy for sails and cordage.

5933 Exceedingly good huckaback is made from it, for towels and common table cloths. The low priced hempen cloths are a general wear for husbandmen, servants, and labouring manufacturers; the better sorts for working farmers and tradesmen in the country; and the finer ones, seven-eighths wide, are pic-

5934. The hemp has few or no diseases.

SUBSECT. 3. The Fuller's Thistle, or Teasel. — Dipsacus fullonum L.; Tetradra Monogyna L., and Dipsaceæ J. Chardon à foulon, Fr.; Kardenistel, Ger.; Diasso, Ital.; and Cardenela, Span. (fig. 799.)

5935. The fuller's thistle is an herbaceous biennial, growing from four to six feet high; prickly or rough in the stem and leaves, and terminated by rough burr-like heads of flowers. It is a native of Britain, flowers in July, and ripens its seed in September. It is cultivated in Essex and the west of England, for raising the nap upon woollen cloths by means of the crooked awns or chaffs upon the heads; which, in the wild sort, are said to be less hooked. For this purpose they are fixed round the circumference of a cylinder, which is made to turn round, and the soil is held against them. In the Journal of a Naturalist we are informed, that the teasel forms an article of culture in cottage gardens in the clothing districts of Gloucestershire.

5936. There are no varieties of the cultivated teasel, and the wild species is not materially different from it, and may be used in its stead, though its chaff is not quite so rigid.

799

5937. The soils on which the teasel grows strongest are deep loamy clays, not over-rich. The situation should be rather elevated, airy, and exposed to the south. In a rotation it may occupy the place of a green and corn crop, as in the first year the plants are treated like turnips, and in the second the crop is ripened. The soil should be ploughed deep, and well comminuted by cross-ploughings, or stirrings with pronged implements, as the cultivator.

5938. The sowing season is the beginning of April: the quantity of seed is from one perch to two pecks per acre, and in quality it should be fresh and plump.

5939. The mode of sowing is almost always broad-cast, but no crop is being adapted for being grown in drills, as the plants may be raised during the summer months; and in the course of the following winter, as about the latter end of February, the land between the plants is to be again worked over by the narrow spades, care being taken that none of the mould falls into the hearts of the plants. Again about the middle of May, when they begin to spindle, another digging over is given, the earth being raised round the root-stems of the plants, in order to support and prevent them from being blown down by the wind. Some cultivators perform more frequent diggings, that the ground may be rendered cleaner and more mellow; consequently the growth of the plants will be the more effectually promoted. This business, in Essex, has usually the name of spudding, and is executed with great despatch by laboriously hew-drawn ploughs.

5940. The after-culture of this crop consists the first year in hoeing and stirring the soil, and in thinning out the plants to the distance of one foot every way, if sown broad-cast, or to the distance of six inches if sown in rows. Vacancies may be filled up by transplanting; and a separate plantation may be made with the thinnings, but these never attain the same vigour as the seedlings. The culture in the second year consists also of hoeing, stirring, and weeding, till the plants begin to shoot.

5941. When the teasel is grown broad-cast, the intervals between the plants are dug by means of spades which have long narrow blades, not more than about four inches in breadth, having the length of sixteen or eighteen inches. With these the land is usually worked over in the intervals of the plants three or four times during the summer months; and in the course of the following winter, as about the latter end of February, the land between the plants is to be again worked over by the narrow spades, care being taken that none of the mould falls into the hearts of the plants. Again about the middle of May, when they begin to spindle, another digging over is given, the earth being raised round the root-stems of the plants, in order to support and prevent them from being blown down by the wind. Some cultivators perform more frequent diggings, that the ground may be rendered cleaner and more mellow; consequently the growth of the plants will be the more effectually promoted. This business, in Essex, has usually the name of spudding, and is executed with great despatch by laboriously hew-drawn ploughs.

5942. The taking of the teasel crop, when no regard is had for seed, commences about the middle of July, when the blossoms begin to fall from the top, or terminating heads of flowers.

5943. It is the best method to have the heads cut as they become ripe; but the work is mostly executed at three times, at the distance of about ten days or a fortnight from each other. It is performed by means of a knife, contrived for the purpose, with a short blade and a string attached to the hilt. This last is done in order that it may be hung over the hand. A pair of strong gloves is likewise necessary. Thus prepared,
the labourer cuts off the ripe heads along the rows or lines with about nine inches of stem, and ties them up in handfuls with the stem of one that is more perfectly ripened. On the evening of the day on which they are cut, they should be put into a dry shed; and when the weather is fine and the air clear, they should be taken out and exposed to the sun daily till they become perfectly dry. Much care must, however, be taken that no rain falls upon them. In doing this, some make use of long small stakes or poles, on which these handfuls are hung during the time of their preparation.

5914. As soon as they are completely dried, they should be laid up in a dry room, in a close manner, till they become tough and of a bright colour, and ready for use. They should then be sorted or separated into three kinds, by opening each of the small bundles. These are distinguished into kings, middlings, and scrubs, according to their different qualities. They are afterwards, the author of The Somerset Report says, made into packs, which, of the first sort, contain nine thousand heads, but when of the second, twenty thousand; the third is a sort of very inferior value. By some, before forming them into packs, they are done up into what are termed staves, by means of split sticks, when they are ready for sale.

5915. The produce of teasel varies from ten to fifteen packs on the acre; nine packs of kings, nineteen of middlings, and two of scrubs, are reckoned a large crop, with a great bulk of haulm. Often, however, the crop fails.

5916. The use of the heads of the teasel has been already mentioned. The haulm is of no use but for burning as manure. Parkinson observes, that this is a sort of crop that may be grown to advantage on many lands, in a rotation, as a fallow to prepare for wheat; and by burning the straw and refuse stuff after the crop is reaped, it will be found not to impoverish, but rather to improve the land. In their young state, the teasel plants stand the winter without danger; and are a good crop for clearing land of all weeds, from their lateness in the process of hoeing, their being few weeds that vegetate at so advanced a season. On all these accounts they become an advantageous crop for the farmer.

5917. To save seed, leave a few of the very best plants uncropped, and then, when the seed is ripe, cut off only the largest and terminating heads, from which the seed is easily separated by beating with flails, and cleaned by the winnowing machine, or a sieve.

5918. The chief injuries to which the teasel is liable are those inflicted on it while young, by the fly and slug.

SUBSEC. 4. Madder.—Rubia tinctorum L.; Tetrandra Monogynia L., and Rubiaceae J. Garance, Fr.; Färberrotte, Ger.; Robia, It.; and Rubia, Span. (fig. 800.)

5949. The dyer's madder has a perennial root, and an annual stalk. The root is composed of many long, thick, succulent fibres, almost as large as a man's little finger; these are joined at the top in a head, like the roots of asparagus, and strike very deep into the ground, being sometimes more than three feet in length. From the upper part (or head of the root) come out many side roots, which extend just under the surface of the ground to a great distance, whereby it propagates very fast; for these send up a great number of shoots, which, if carefully taken off in the spring soon after they are above ground, become so many plants. It is a native of the south of Europe, flowers in June, and seeds soon afterwards; but by them it is never propagated. Madder is mentioned by the Greeks as a medical plant, but when it was first used in dyeing is uncertain. It has been cultivated in Holland and Flanders, and other parts of the Continent, for the latter purpose for many centuries, and has been tried in this country; but unless the importation of the root from the Continent be entirely prevented, it will not answer. Its culture has been attempted at different times when our commerce with the Dutch was interrupted, or when they raised the price of the article exorbitantly high. At present it may be imported not only from Holland, but from France, Italy, and Turkey.

5950. The soils most suited to the cultivation of madder are deep, fertile, sandy loams, not retentive of moisture, and having a considerable portion of vegetable matter in their composition. It may also be grown on the more light descriptions of soil, of sufficient depth, and in a proper state of fertility.

5951. The preparation of the soil may either consist in trench ploughings, lengthwise and across, with pronged stirrings, so as to bring it to a fine tilth; or, what will often be found preferable, by one trenching two feet deep by manual labour.

5952. The sets or plants are best obtained from the runners, or surface-roots of the old plants. These being taken up, are to be cut into lengths of from six to twelve inches, according to the scarcity or abundance of runners. Sets of one inch will grow if they have an eye or bud, and some fibres; but their progress will be injuriously slow for want of maternal nourishment. Sets may also be procured by sowing the seeds in fine light earth a year before they are wanted, and then transplanting them; or sets of an inch may be planted one year in a garden, and then removed to the field plantation.
5953. The season of planting is commonly May or June, and the manner is generally in rows nine or ten inches asunder, and five or six inches apart in the rows. Some plant promiscuously in beds, with intervals between, out of which earth is thrown in the lazy-bed manner of growing potatoes; but this is unnecessary, as it is not the surface, but the descending, roots which are used by the dyer.

5954. The operation of planting is generally performed by the dibber, but some lay-plant them by the aid of the plough. By this mode the ground is ploughed over with a shallow furrow, and in the course of the operation the sets are deposited in each furrow, leaning on and pressed against the furrow-slice. This, however, is a bad mode, as there is no opportunity of firming the plants at the roots, and as some of the sets are apt to be buried, and others not sufficiently covered.

5955. The after-culture consists in hoeding and weeding with stirring by pronged hoes, either of the horse or hand kind. Some earth up, but this is unnecessary, and even injurious, as tearing the surface-roots.

5956. The madder-crop is taken at the end of the third autumn after planting, and generally in the month of October. By far the best mode is that of trenching over the ground, which not only clears it effectually, but fits it at once for another crop. Where madder, however, has been grown on land prepared by the plough, that implement may be used in removing it. Previously to trenching, the haulm may be cleared off with an old scythe, and carted to the farmery to be used as litter to spread in the straw-yards.

5957. Drying the roots is the next process, and, in very fine seasons, may sometimes be effected on the soil, by simply spreading the plants as they are taken up; but in most seasons they require to be dried on a kiln, like that used for malt or hops. They are dried till they become brittle, and then packed up in bags for sale to the dyer.

5958. The produce from the root of this plant is different according to the difference of the soil, but mostly from ten to fifteen or twenty hundred weight where they are suitable to its cultivation.

5959. In judging of the quality of madder-roots, the best is that which, on being broken in two, has a brightish red or purplish appearance, without any yellow cast being exhibited.

5960. The use of madder-roots is chiefly in dyeing and calico-printing. The haulm which accumulates on the surface of the field, in the course of three years, may be carted to the farm-yard, and fermented along with horse-dung. It has the singular property of dyeing the horns of the animals who eat it of a red colour.

5961. Madder-seed in abundance may be collected from the plants in the September of the second and third years; but it is never so propagated.

5962. Madder is sometimes blighted; but in general it has few diseases.

SUBSECTION 5. Woad. — Isatis tinctoria L. ; Tetradynamia Siliquosa L., and Cruciferae J. Pastel or Guede, Fr.; Woold, Ger.; Guede, Ital.; and Gualda, Span. (fig. 801.)

5963. The common woad is a biennial plant with a fusiform fibrous root, and smooth branchy stem rising from three to five feet in height. It is a native, or naturalised in England, flowers from May to July, and its seeds are ripe from July to September. It has been cultivated in France for an unknown length of time, and was introduced to England in 1582, and grown with success. It is now chiefly cultivated in Lincolnshire, where it is a common practice to take rich flat tracts near rivers, at a high price, for the purpose of growing it for two or four years. Those who engage in this sort of culture form a sort of colony, and move from place to place as they complete their engagements. It is sometimes, however, grown by stationary farmers. The leaves are the parts of the plant used, and it is considered a severe crop.

5964. There is a variety of woad called the Dalmatian, described by Miller, and also a wild sort; but only the common is cultivated in this country.

5965. The soil for woad should be deep and perfectly fresh, such as those of the rich, mellow, loamy, and deep, vegetable kind. Where this culture is carried to a considerable degree of perfection, as in Lincolnshire, the deep, rich, putrid, alluvial soils on the flat tracts extending upon the borders of the large rivers, are chiefly employed for the growth of this sort of crop; and it has been shown by repeated trials that it answers most perfectly when they are broken up for it immediately from a state of sward.

5966. The preparation of the soil, when woad is to be grown on grass land, may either be effected by deep ploughings, with the aid of the winter's frost, cross ploughing and
harrowing in spring; by deep ploughing and harrowing in spring; by paring and burning; or by trench-ploughing, or spade trenching.

5971. The first mode appears the worst, as it is next to impossible to reduce old turf in one year, and, even if this is done, the danger from the grub and wire-worm is a sufficient argument against it. By ploughing deep in February, and soon afterwards sowing, the plants may germinate before the grub is able to rise to the surface; by trench-ploughing, the same purpose will be better attained; and, best of all, by spade trenching. But a method equally effectual with the first, more expeditious, and more destructive to grubs, insects, and other vermin, which are apt to feed on the plants in their early growth, is that of paring and burning. This is, however, churlily practiced where the sward is rough and abounds with rushes, seige, and other plants of the coarse kind, but it might be had recourse to on others, with benefit.

5968. The time of sowing may be extended from February to July. Early sowing, however, is to be preferred, as in that case the plants come up stronger and afford more produce the first season.

5969. The mode of sowing is generally broad-cast, but the plant might be most advantageously grown in rows and cultivated with the horse-hoe. The rows may be nine inches or a foot apart, and the seed deposited two inches deep. The quantity of seed for the broad-cast method is five or six pounds to the acre; for the drill mode, two pounds are more than sufficient, the seed being smaller than that of the turnip. New seed, where it can be procured, should always be sown in preference to old; but, when of the latter kind, it should be steeped for some time before it is put into the ground.

5970. The after-culture of the wood consists in hoeing, thinning, prong-stirring, and weeding, which operations may be practised by hand or horse tools, * in the culture of teasle.

5971. Gathering the crops. The leaves of the spring-sown plants will generally be ready towards the latter end of June or beginning of July, according to the nature of the soil, season, and climate; the leaves of those put in at a later period in the summer are often fit to be gathered earlier. This business should, however, constantly be executed as soon as the leaves are fully grown, while they retain their perfect green colour and are highly succulent; as when they are let remain till they begin to turn pale, much of their goodness is said to be expended, and they become less in quantity, and of an inferior quality for the purposes of the dyer.

5972. In the execution of this sort of business, a number of baskets are usually provided in proportion to the extent of the crop, and into these the leaves are thrown as they are taken from the plants. The leaves are detached from the plants by grasping them firmly with the hand, and giving them a sort of a sudden twist. In favourable seasons, where the soils are rich, the plants will often rise to the height of eight or ten inches; but in other circumstances, they seldom attain more than four or five: and where the lands are well managed they will often afford two or three gatherings, but the best cultivators seldom take more than two, which are sometimes mixed together in the manufacturing. It is necessary that the after-croppings, when they are taken, should be constantly kept separate from the others, as they would injure the whole if blended, and considerably diminish the value of the produce. It is said that the best method, where a third cropping is either wholly or partially made, is to keep it separate, forming it into an inferior kind of wood.

5973. The produce is mostly from about a ton to a ton and a half of green leaves. The price varies considerably; but for wood of the prime quality, it is often from twenty-five to thirty pounds the ton, and for that of an inferior quality six or seven, and sometimes much more.

5974. To prepare it for the dyer, it is bruised by machinery to express the watery part; it is afterwards formed into balls and fermented, re-ground, and fermented in vats, where it is evaporated into cakes in the manner of indigo. The haunm is burned for manure or spread over the straw-yard, to be fermented along with straw-dung.

5975. The use of woad in dyeing is as a basis for the black and other colours.

5976. To save seed, leave some of the plants undamaged of their leaves the second year, and when it is ripe, in July or August, treat it like turnip-seed.

5977. The only diseases to which the woad is liable are the mildew and rust. When young it is often attacked by the fly, and the ground obliged to be re-sown, and this more than once even on winter-ploughed grass lands.

Subsect. 6. Weld, or Dyer's Weed. — Wél, Oé dre’s ould; Dodecandria Tríngiá L., and Resédéa Lindl. Gaude, Fr.; Waud, Ger. (fig. 802.)

5978. Weld is an imperfect biennial, with small fusiform roots, and a leafy stem from one to three feet in height. It is a native of Britain, flowers in June and July, and ripens its seeds in August and September. It is cultivated in a few places in England, and chiefly in Essex, for its spike of flowers, and sometimes also for its leaves, both of which are used in dyeing. Its culture may be considered the same as that of woad, only being a smaller plant it is not thinned out to so great a distance. It has this advantage for the farmer over all other colouring plants, that it only requires to be taken up and dried, when it is fit for the dyer. It is, however, an exhausting crop.

5979. Weld will grow on any soil, but fertile loams produce the best crops. In Essex, it is grown on a stiff loam, moderately moist.
5983. The produce of weld depends much on the nature of the season; but from half a load to a load and a half per acre is the quantity most commonly afforded. It is usually sold to the dyers at from five or six to ten or twelve pounds the load, and sometimes at considerably more. It is mostly bought by persons who afterwards dispose of it to the dyers. The demand for it is sometimes very little, while at others it is so great as to raise the price to a high degree. It is sometimes gathered green and treated like woad or indigo; but in general the dried herb is used by the dyers in a state of decoction.

5984. The use of weld in dyeing is for giving a yellow colour to cotton, woollen, mohair, silk, and linen. Blue cloths are dipped in a decoction of it, which renders them green; and the yellow colour of the paint called Dutch pink is obtained from weld.

5985. To save seed, select a few of the largest and healthiest plants, and leave them to ripen. The seed is easily separated.

5986. The chief disease of weld is the mildew, to which it is very liable when young, and this is one reason that it is often sown with other crops.

5987. The bastard saffron is an annual plant, which rises with a stiff ligneous stalk, two feet and a half or three feet high, dividing upwards into many branches, with ovate pointed sessile leaves. The flowers grow singly at the extremity of each branch; the heads are large, enclosed in a scaly calyx; each scale is broad at the base, flat, and formed like a leaf of the plant, terminating in a sharp spine. The lower part of the calyx spreads open, but the scales above closely embrace the florets, which stand out nearly an inch above the calyx; these are of a fine saffron colour, and this is the part which is gathered for the use of the dyer.

5988. It grows naturally in Egypt and some of the warm parts of Asia; but, being an annual, our summers admit of its going through a course of existence in this country. Sown in April, it flowers in July and August, and the seeds ripen in autumn; but if the season proves cold and moist, when the plants are in flower, there will be no good seeds produced; so that there are few seasons wherein the seeds of this plant come to perfection in England.

5989. It is cultivated in great plenty in Germany, and was formerly grown in England. In Houghton's Collections, it is related by a gentleman, in 1684, that twenty-five acres in the Vale of Evesham, in Gloucestershire, were sown with this seed; the soil a mixed sand of about fifteen shillings an acre in value; it bore a crop of wheat the year before, was dressed for barley, and had a harrowing extraordinary. This piece of ground was taken for two years by an adventurer in this seed, at the rate of twenty-five pounds per acre, in consideration that this plant is said to be a great impoverisher of land. He sold the flowers in London for 10l. per pound; a price, he said, much below his expectation. He gained above thirty shillings an acre clear profit, except the price of the seed; but of this there was a plentiful return (about one hundred and forty bushels), which, had it been well managed, would have amounted to a considerable value. Like
most other manufacturable plants is considered an impoverisher of the ground; both by exhausting it, and by affording but little haulm as manure.

5990. The soil it requires is light, and the preparation and culture, according to Von Thaer, equal to that of the garden. The seed is sown in rows, or deposited in patches two feet apart every way, and when the plants come up, they are thinned out, so as to leave only two or three together. The soil is stirred and waded during summer. In August the flowers begin to expand; the petals of the florets are then to be cut off with a blunt knife, and dried in the shade, or on a kiln, like the true saffron. This operation is performed in the early part of the day, and continued daily till October. The plants are then pulled up, sheaved and shocketed, and threshed for their seed.

5991. The use of the flowers of bastard saffron is chiefly in dyeing. It is also put in soups, pies, and puddings, like the leaves of the marigold or the common saffron. The oil produced from the seed is used both in medicine and painting. The stalks of the plants are commonly burnt for manure.

SUBJECT. 8. Various Plants which have been proposed as Substitutes for the Thread and Dyeing Plants grown in Britain.

*5992. Though few of these are likely to come into cultivation, yet it may be useful to notice them, with a view to indicating our resources for extraordinary occasions; to leading the young cultivator to reflect on the richness of that immense store-house, the vegetable kingdom; and to pointing out sources of experiment and research for the amateur agriculturist. Every kind of limitation has a tendency to degrade the mind, and lessen enterprise. The plants to be here enumerated, naturally arrange themselves as thread plants and colouring plants.

5993. The thread plants that have been tried are the Asclepias syriaca, Urtica dioica (or nettle), Urtica canadensis (or Canadian nettle), the Spárium juncurnimum, and Cytisus scoparius (brooms), Epilobium angustifolium, Eric phorurn polystachyon, &c. The Asclepias syriaca, Syrian swallow-wort, or Virginian silk, is a creeping rooted perennial, with strong erect stems from four to six feet high. It is a native of Virginia, and flowers in July. The flowers are succeeded by pods, containing a down or cotton, which the poor people in Virginia collect and use. In Germany, and especially at Leignitz, attempts were made, in 1790 and 1800, Von Thaer informs us, to cultivate the plant as a substitute for cotton. It was found to grow readily on a poor soil; but the growers could not undersell the importers, nor produce so good an article nor cotton grass, grown abundantly in our bogs, and its seeds are furnished with a cottony substance, gathered by the country people to stuff pillows, &c. This substance has been spun and woven into very good cloth. The common nettle affords a fibre which has also been spun and manufactured. The fibre of the Spárium juncurnimum, rush, like the common broom, is found in great abundance in the south of Europe, but quite hardy in Britain, is made into very good cloth both in the south of France and in Spain. The fibre of the common broom makes an inferior description of cordage in the former country. The Epilobium angustifolium, and other species of willow herb, common by the sides of brooks, afford a very good fibre, as do a great variety of plants: and in Sweden a strong cloth is made from the stem of the wild hop Humulus lupulus, and the same thing has been done in England. (Trans. Soc. Arts 1781.) Indeed there are few plants the fibres of which might not be separated and rendered available for the purpose of spinning the threads for weaving into cloth, or of making for printing-paper. The fibres of nettles, square-stemmed herbaceous plants answer for the former purpose; and both the fibres and bark of several plants, for the latter. The fibres of all the herbaceous mollows are uncommonly white, and finer than camel's hair; and in Germany they are used in making an imitation of camel's hair, for the purpose of the borders of the table or the kettledrums are amongst the strongest. The last described: those, with a little beating, rubbing, and shaking, are easily separated from the strawy part, when the plant has been steeped ten or twelve days in water; or is damp and in a state approaching to fermentation, or what is commonly called retting. When stretched or pulling it through becks, or iron combs, it coarsens, and then finer fibres appear to the dressing of bean hemp; and is perhaps the easiest mode of separating the filaments from the thin membrane that surrounds them. The fibre of the common nettle is very similar to that of hemp or flax, inclining to either according to the soil and different situations in which it grows; and it has been shown by experiment, that they may be used for the same purposes as hemp or flax, from cloth of the finest texture down to the coarsest quality, such as sailcloth, sacking, cordage, &c. (Smith's Mechanic, vol. ii.) It might be worth the attention of any one who had leisure to collect a few, say only two, stalks, of a great number of species from a botanic garden, during a sufficient time in soft soap and warm water, and prove their absolute and comparative value as fibre plants.

5994. Brown flax is prepared by steeping the twigs or most vigorous shoots of the former year, for two or three weeks, more or less, in water; acidifying the water, or in stagnant stagnant water, or by boiling them for about an hour in water. This done, the flax comes freely from the twigs; and, where there is no moisture for the purpose, they may be easily peeled or stripped off, by children or others, at any time when not quite dry, in the same way as hemp is peeled from the stalks. Being cleared of the

5995. Of colouring plants, the number that may be, and even are employed, is almost endless. The reader has only to look into any botanical catalogue, and observe the number of plants whose specific names are formed from the adjective tintibus; and these, though numerous, are still only a small part. On looking into the Flora Britannica, and the Flora Sæcule, he will be surprised at the number of plants, even trees and ferns, which are used for dyeing. A number have been tried in this country and given up; as an instance, we mention ĥalium verum, which, in 1785, when the price of madder was high, was tried under the authority of the privy council for the trade. The Oen tinecum, Genista tinctoria, Rhinamus chloroticus and infernibus, and Plantago Pavium, are cultivated in France as dyeing plants.

SECTION II. Plants cultivated for the Brewery and Distillery.

5996. Of plants grown expressly for their use in the brewery, the only one of consequence is the hop; the anise and caraway are grown on a very limited scale for the distillery.
we had been in a measure pined, and in a great measure starved, which is just answerable to the principles of those men who cry down all devices or ingenious discoveries as projects, and thereby stifle and check improvements."

5997. The hop has long been cultivated extensively in many parts of England, but not much in Scotland or Ireland. According to Brown, hops are not advantageous in an agricultural point of view; because much manure is abstracted by them, while little or none is returned. They are an uncertain article of growth, often yielding large profits to the cultivator, and as often making an imperfect return, barely sufficient to defray the expenses of labour. In fact, hops are exposed to more diseases than any other plant with which we are acquainted; and the tralee, the worm, and other injurious insects are exercised within the British dominions. (Brown.) Parkinson in a paper on the culture of the hop in Nottinghamshire, published in the Farm. Mag. vol. xvi., observes that "the hop is said to be a plant very properly named, as there is never any certainty in cultivating it."

6000. There are several varieties of the hop. The writer of The Synopsis of Husbandry distinguishes them under the titles of the Flemish, the Canterbury, the Goldings, the Farnham, &c., and says that the Flemish is held in the lowest estimation of any.

6001. The Flemish hop, he says, is of a smaller size, of a much closer contexture, and of a darker green colour, than any of the rest, and grows on a red bind; and has so near an affinity to the wild or hedge-hop, that it would never answer for cultivation, did it not possess the property of resisting the blast with greater vigour than the other kinds; so that, in years when these last are covered with flies and hee, the Flemish hop appears strong and healthy. At picking time, likewise, this kind of hop, he says, takes less damage, either by the sun or rain, than any other; and upon these accounts, it may answer the views of the planter to have a few acres of it, which will secure him a crop in a blasting season, when those of the more valuable class are destroyed, so as to be worth nothing.

6002. The soils most favourable to the growth of hops are clays and strong deep loams: but it is also of great importance that the subsoil should be dry and friable; a cold, wet, tenaceous, clayey understratum being found extremely injurious to the roots of the plants, as, when they penetrate below the good soil, they soon become unproductive, and ultimately decay.

6003. A chalky soil, Bannister says, is, of all others, the most inimical to the growth of this vegetable; the reason of which he takes to be the dry and parching quality of the chalk, by which the roots are prevented from absorbing a quantity of moisture, equal to the supply to the vine or bind with sap during its growth; for though a dripping summer is by no means kindly to the welfare of the hop, yet since the soil in a healthy state is very luxuriant, and furnished with a large abundance of branches, leaves, fruit, &c., it follows that the demand of moisture from the soil must be proportionably great to preserve the plant in health and vigour, and for this reason the ground ought not to be deficient in natural humidity. Hence we generally find the most luxuriant vine growing on deep and rich land, as moulds, &c., and in those grounds it is common, he says, to grow a load on an acre. But it is to be observed, however, that the abundance of fruit is not always in proportion to the length of the vines; for those soils which are from their fertility, cause a large growth of vine are more frequently attacked by the blast, than land of a shallower depth where the vine is weaker and less luxuriant.

6004. But though rich moulds generally produce a larger growth of hops than other soils, there is one exception to this rule, where the growth is frequently only half that on a more equal one. This is on the rocks in the neighbourhood of Maidstone, in Kent, a kind of shaly ground, with an understratum of stone. On these rocks there is a large extent of hop-garden, where the vines run up to the tops of the longest poles, and the increase is equal to that on the most fertile soil of any kind. This is on the rocks in the neighbourhood of Maidstone, in Kent, a kind of shaly ground, with an understratum of stone. On these rocks there is a large extent of hop-garden, where the vines run up to the tops of the longest poles, and the increase is equal to that on the most fertile soil of any kind.

6005. The most desirable situation for a hop plantation is ground sloping gently towards the south or south-west, and screened, by means of high grounds or forest-trees, from the north and north-east. At the same time it ought not to be so confined as to prevent that free circulation of air which is indispensably necessary where plants grow so close together. A free and even current of air is springing in a hop-ground, not only conduces to the health and vigour of the plants, but also prevents the crops from being brightened, or what the hop-farmers call fire-blacked, which often happens towards the middle of a large close planted hop-ground; while the outside, in consequence of the more free circulation of air that takes place, receive no injury whatever.

6006. Bannister asserts, that those fields which lie within a few miles of the sea, or in the neighbourhood of marshy or fenous levels, are seldom favourable to the growth of hops, as such grounds generally carry a damp or a blustering air in a blasting year; and, though, from the fertility of the soil, they may perhaps bring a plentiful crop in those seasons when the growth is general, such a situation is eligible for a hop ground. In Worcestershire and Herefordshire hops are very generally grown between the rows of fruit trees in dug or ploughed orchards.
6007. In preparing the soil previously to planting, considerable attention is necessary, by folowing, or otherwise, to destroy the weeds, and to reduce the soil to a pulverised state as possible. The ridges should also be made level, and dung applied with a liberal hand. The most effectual preparation is trenching either by the plough or by manual labour.

6008. The mode of planting is generally in rows, making the hills six feet distant from each other; though there are some people who, from avaricious motives, prefer a five-feet plant. But as this vegetable, when advanced in growth, produces a large redundance of bind or vine, and leaves, it should seem that six feet cannot be too wide a distance; and that those which are planted closer will, from too confined a situation, be prevented from enjoying a free circulation of the air; from which much injury may proceed, as blasters, mildews, moulds, and other accidents, not to mention the disposition of the vine to house or grow together at the tops of the poles, whereby the hops are so overshadowed as to be debarr'd the influence of the sun, and prevented from arriving at half their growth.

6009. As the planters differ in the number of hills to be made on the same given quantity of land, so are they no less capricious as to the manner of placing them, some choosing to set them out with the most cautious regularity in rows of equal distances, whilst others prefer planting in quincunx. The former method has this advantage; that the intervals may, in the early part of the summer, be kept clean by means of the cultivator and harrow; but, in the latter method, these implements are rendered inadmissible by the irregular station of the plants; and, in the ground must be tiled with the hoe at a greatly increased expense, as the same labour might be performed to as much advantage with one horse, a man, and a boy, who will do more work in a day than half a dozen labourers can with a hoe.

6010. The ordinary season for planting is spring, in February or March; but if bedded plants, or such as have been kept for one summer in a garden, are used, then by planting in autumn some produce may be had in the succeeding year. But, according to the author of The New Farmer's Calendar, "the time for planting is commonly that of dressing and pruning the old vines; each cuttings may be had, which is in March or April; but when root-sets are used, as on the occasion of grubbing up an old plantation, October to the beginning of November. But at whatever period they are planted, great care should be taken that the same sorts be planted together, as by this means there are advantages derived in their after-culture."

6011. The plants or cuttings are procured from the old stocks, and each should have two joints or eyes; from the one which is placed in the ground springs the root; and from the other the stalk, provincially the bind. They should be made from the most healthy and strong binds, each being cut to the length of five or six inches. Those to be nursed are planted in rows a foot apart, and six inches asunder, in a garden; and the others at once where they are to remain.

6012. The mode of performing the operation of planting in Kent is as follows:—

6013. The land having been previously cleared and prepared, dung is laid on the field in small heaps near the places where it is proposed to plant the hop slips or sets. These places are commonly marked on, by inverting a number of stakes at proper and regular distances; that done, small pits are formed by taking out a spit, or spade's depth of earth; and the earth below being gently loosened, a certain quantity, about half a bushel, is thrown into each of these pits; and so much added as to form a small hilllock. On this hilllock, five, six, or seven sets, procured from the roots or shoots of the old stock, are dibbled in. The plants are placed in a circular form towards the top of the hilllock, and at the distance of five or six inches from each other. They are made to incline towards the centre of the hilllock, where another plant is commonly placed.

6014. Another mode of planting is as follows:—Strike furrows with the plough at equal distances of eight feet; when finished, repeat the same across in the opposite direction, which will divide the piece into eight squares, in the two by four where each other, and the furrows or cuts may be admitted between the rows both ways. According to the Suffolk husbandry, the plantations are formed into beds sixteen feet wide, by digging trenches about three feet wide, and two or three feet deep; the earth that comes out being spread upon the beds, and the whole dug and levelled. Upon this they, in March, form the holes six feet asunder every way, two inches in diameter, and a spat deep, by which three rows are formed on each bed. Into each hole they put about half a peck of very rotten dung, or rich compost, and scatter earth upon it; and in each they plant a set, drawing earth enough to it afterwards to form something of a hilllock.

6015. An interval crop is generally taken in the first summer of a hop plantation. Beans are very generally grown; and Bannister is of opinion that two rows of beans may be planted in each interval without any damage to the hops, whether bedded sets or cuttings. In the latter case, this method may be pursued in the second year, at the end of which the vine from the cuttings will not be in a more forward state than that from the bedded sets in the first autumn after planting. Others, however, think that neither beans, cabbages, nor other plants, except onions, should be put in.

6016. The after-culture of the hop, besides the usual processes of hoeing, weeding, stirring, and manuring, includes earthing-up, staking, and winter dressing.

6017. Hoeing in hop plantations may always be performed by a horse implement; and one in use for this purpose in the hop counties, and of which the expanding horse-hoe fig. 357 is an improvement, is known by the name of hop-nidget. When the hop-stools are formed in the angles of squares, the intervals may be hoed both lengthwise and across, and thus nothing is left to be performed by manual labour but pulling out weeds which may rise in some places which may rise in any place within the square. The implement is neither too wide as to disturb the earth of any depth, either in summer or winter; and, with the plough, the surface could be changed at discretion. Once going and returning would effect this, either by the paring or clearing out;
that is, forming either a rightlet, or gutter between the rows, both lengthwise and across. Twice or thrice-going in the same direction would also succeed, and would be the preferable mode of covering in manure.

The growth of hops is a very important branch of agriculture. The roots, or rhizomes, are planted in a trench or bed, or mound, of the various moulds and manures; others, composts of earth and dung; and a few, littery dung. In laying it on, many prefer the autumn to the spring, and heap it on the hills without putting any between the rows. Others put it all between the rows, alleging that laying it on the rhizomes of the hop is a beneficial operation, and that when mixed with earth, hinders the plants from coming up. A great deal will be found in favour of, and against each of these modes, in the numerous works on the culture of the hop, which have been written during the last three centuries; but it must be obvious to any person generally conversant with horticulture, that for laying the dung it must be with certainty the best season for laying it on; that little benefit can be derived by the roots when it is laid on the hills, and, consequently, that it ought to be turned into the soil between the rows by the plough. Fifty cart-loads of dung and earth, or thirty, is, in three years, to prevent a root being barren for two years in three years. Too much dung renders the hops what is called mouldy, and too little causes the crop to be poor and more liable to be eaten by insects.

6530. Earthing-up commences the first May after planting, whether that operation be performed in spring or autumn. In the young hops the roots have made some progress, and the earth is then drawn up to their roots from the surrounding intervals, in order to strengthen them. The next earthing-up is in autumn, when the hills are by some covered with compost or manure; but by such prefer plunging in the earth, especially if this earth be the hard earth that rises up in the hills; it may be also used in spring, and generally in February, chiefly to retard the plants, as that is found to render them less liable to disease; for the shoots not beginning to grow till the weather is warm, they then shoot more rapidly. In April and May, their progress is allowed to continue in an inch in the hour. The only essential earthing up, however, are those given the first year in May, and those given annually after the operation of dressing, whether in autumn or spring, which indeed may be called replacements of earth, rather than earthing up.

6531. In dressing the hop plants, the operations are confined to twisting and removing the haulm, to which some add cupping or earthing-up in autumn.

6532. The operation of cupping is confined to such plants as have already commenced to form flowers and fruitlets, and are not to be produced to any crop that season. It is performed in the end of June or in July. The flowers are tied together in small bunches or knots; so that, by this discouraging their growth, the roots are enabled to spread out more vigorously, and to acquire strength preparatory to the crop of the winter branch of the plant. It is performed by clipping the tendril, or by tying the flowers together, and carrying it off the field for litter or manure. After this operation, some prefer the top shoots to be allowed to remain; but this does not appear necessary, and is in many cases left undone.

6533. The first dressing commences in the middle of July, and consists of those plants from bedded sets in the preceding autumn, consisting in applying three or four half poles, that is, poles a yard long, to each hill, to cut off the growths, and prevent the shoot from remaining the haulm in autumn, as in the other cases.

6534. The operation of dressing of established plantations consists of what is properly called picking. This operation is generally

6535. The yearly operation of stocking or setting the poles commences towards the end of April, or at whatever period, earlier or later, the shoots may have risen enough for it.

6536. The operation is performed with the pole, or pole-vine, reeking its head against the velvet bark of the male, while others hold their aloof, from chilly smooth-barked or grown poles. It is more probably as far more difficult than once we found to keep the hopping with equal auburnness to the smooth-barked pole and the rough-barked pole or sugars, and with respect to chilly smooth poles, the pole is known to thrive with as much vigour round iron or copper wire as round any woods.

6537. In regard to the size of the pole, hops, likewise, it is well known the interspice choice or appreciation, with respect to the thickness of their support; embracing, with greater readiness, a pole that is moderately small, than one which is large. The pole is often of a long height, and the pole, at the best end, may be set down at from six to nine inches from the top of the hill, the poles being divided into the length from fifteen to twenty feet, or upwards. Different grades are to be purchased in the usual market, the poles being in the neighbourhood of Maidstone, the poles of green hops stand, in general, from fourteen to sixteen feet above the hill, and in the east part of England, from two to three feet. But, on weaker lands, poles are not seen to rise more than ten or twelve feet above, and on these, on account of the pole, the poles, by decaying at the roots, grow shorter, and, in a course of years, get too short for strong vines, on rich lands. They are, in this case, sold, and transferred to less productive lands, and vines of hammer growth.

6538. Your pole has sometimes the bark chafed off, under an idea that it saves them from the worm; while some men are of opinion that there is a warmth in the bark, which is acceptable to the young vines; and although in two or three years the bark has been more or less chafed off, the pole, at the best end, may be set down at from six to nine inches from the top of the hill, the poles being divided into the length from fifteen to twenty feet, or upwards. Different grades are to be purchased in the usual market, the poles being in the neighbourhood of Maidstone, the poles of green hops stand, in general, from fourteen to sixteen feet above the hill, and in the east part of England, from two to three feet. But, on weaker lands, poles are not seen to rise more than ten or twelve feet above, and on these, on account of the pole, the poles, by decaying at the roots, grow shorter, and, in a course of years, get too short for strong vines, on rich lands. They are, in this case, sold, and transferred to less productive lands, and vines of hammer growth.

6539. Wire or copper rope have been tried as substitutes for wooden poles, but have not obtained much favour, except among some of the horticultural societies, or in the distant parts of France; but the copper rope, when well treated in this way, we do not think it any improvement. The wires are stretched horizontally in the direction of the rows of plants, the first wire five feet from the ground, the second one four feet, and so on to the height of height of height. The plants are tied to the lowest wire by short sticks, and left to twist up or along the others at pleasure.
6034. Tying the shoots or vines to the pole is the last operation in the after or summer culture of the hop. This requires the labour of a number of persons, generally women, who tie them in several different places with withered rushes, but so loosely as not to prevent the vines from advancing in their progress towards the top. The vines have got out of the ground, proper persons go round, with standing ladders, and tie all such as appear inclined to stray.

6035. The season for this operation varies from the middle of June to the end of June, and one important part of the operation is to tie the shoots so that the vine should always be examined, as it is well known that the branch or shoot is liable to be over-tied, and the results are fatal, if any fruit. The scain shoots, where the hills are not overladen with hops, are, in the month of June, thickly entwined over, and forth a very luxuriant vine, may with safety be tied up: but when the hills are strongly loaded, the tying of the shoots, where the vine is always strong and vigorous, and where the failure in the crop chiefly arises from this cause, the greatest precaution is to be taken in tying the shoots. The tying of a proper vine; especially in years which may be supposed to be barren, is most important, as even a strong and healthy vine may be ruined by a winter that is very severe. The best weather has prevailed throughout the month of March, whence one may suppose that the same weather will happen during the course of the month of May, which never fails to bring the long-winged fly. In such a season it would be well worth while to eradicate all the vine which first appears, and treat to a later date. The vines will not only be more healthy, but there will be no need of the laying by of the hops in May. This hint was taken from the observations made in such plantations where the hops are laid by on the poor and thin banks where the soil is naturally backward, and seldom becomes fit for the tires, till towards the latter part of June, when the weak shoots will have advanced nearly to the tops of the poles, and to an insufficient degree, which seems proper for this; whereas, to those who have not been conversant in these matters, and to those who have not plantations of hops, the putting of the vine at that time will be green and flourishing; it may be easily from 12 months to 18 months old; which is a good saving of hops, and will greatly help towards a saving of hops in years when the blast is most prevalent.

6036. Taking the crop is a most important operation in the hop economy

6037. Hops are known to be ready for pulling when they acquire a strong scent, and the seeds become firm and of a brown colour, which, in ordinary seasons, happens in the first or second week of September.

When the pulling season arrives, the utmost assiduity is requisite on the part of the planter, in order that the different operations may be carried on with regularity and on time; as the least neglect, in any department of the business, proves in a great degree ruinous to the most abundant crop, especially in precarious seasons. Gailes of wind at this season, by breaking the lateral branches, and bruising the hops, prove more injurious as a long and severe course of rainy weather, which never fails to spoil the colour of the crop, and thereby render it less saleable.

6038. As a preparation for pulling the hops, frames of wood, in number proportioned to the size of the ground, and the pickers to be employed, are laid in convenient enclosure. The hops, having been most exposed to the influence of the sun, is soonest ready for pulling. It is generally said in the hop-garden that there is no operation more simple in the construction, being only four pieces of boards nailed together in the form of a square, of seven or eight feet long, three feet broad, and about the same height. A man always attends the pickers, whose business it is to pull the hops, and also to watch and pick up those on the frames to be picked. Commonly two, but seldom more than three men are allowed to pick the hops together, as the pickers, women, girls, and boys, are employed at the same fractions, as well as the men. This is the case, the man who sorts the poles, are called a wet. The hops, after being pulled, and those of the different varieties, or stalks, are dropped by the pickers into a large cloth, hung all round within the frame, and carried by a porter or bearers, and the hops laid on a kid to be dried. This is always done on a very stormy day, and in the most exposed state of the field, in order to sustain considerable damage, both in colour and flavour, if allowed to remain long in sacks in the green state in which they are pulled. In very warm weather, and when they are pulled in a moist state, they will often heat in five or six hours; for this reason the kilns are kept constantly at work, both night and day, from the commencement to the conclusion of the hop season.

6039. To set on a sufficient number of hands is a matter of prudence, in the picking season, that the hops or kilns may never be unsupplied with hops; and if it is found that the hops are not thicker than could have been expected, and that there are more gathered in a day than can be conveyed to market, or that the worst pickers may be discharged; it being very prejudicial for the green hops to continue long in the sacks before they are put on the oast, as they will in a few hours begin to heat, and acquire an unsightly appearance, and those in a longer time, as the weight of these, if they could be dried, especially if the season be very moist, in a wet hopping, it is no easy matter to prevent the kiln from being overrun, while there are likely to be some, and perhaps many, to be left in the fields, if the weather had been dry, because in a wet cold time the hops require a longer time to dry, and in order that the superabundant mid-nature may be dried up. It is very necessary in this case that each breakfast should be divided into a number of green pockets or pockets. The number of kilns in a poke ought never to exceed eleven; but when the hops are wet, or likely to become so, some time before they go on the kiln, the better way is to put only eight hundred in a sack, pocket, or poke.

6040. Daundat assures that diligent pickers, when the hop is tolerably well matured, and is in the proper condition, are picked off in the heat of the sun, when, dry, will weigh about one hundred weight, and is common to be unsized or shrunken, on the best grounds by the bushel. The price is extremely variable, depending no less on the goodness of the crop than on the abundance or scarcity of labourers. The greatest part of the hops cultivated in England is picked by people who make a practice of coming annually from the remote part of Wales for that purpose.

6041. The operation of drying hops is not materially different from that of drying malt; and the kilns, or oasts, are of the same construction.

6042. The hops are spread on a hair-cloth, and from eight to ten, sometimes twelve, inches deep, according to the ripeness of the hops. A thorough knowledge of the best method of drying hops can only be acquired by long practice. The general rules are, to begin with a slow fire, and to increase it gradually, till, by the heat on the kiln, and the warmth of the hops, it isknown to be gaining steady fire is continued for about four hours, according to the state or circumstances of the hops, by which time the ends of the hop-stalks become quite shrivelled and dry, which is the chief sign by which to ascertain that the hops are properly and sufficiently dried. They are then taken off the kiln, and laid in a large room or lot till they become quite cool. They are now in condition to be put into bags, which is the last operation the planter has to perform previously to sending his crop to market.

6043. When hops are dried on a cockle-bast, sea-coal is the usual fuel, and a childron is generally employed. On the hair kilns, charcoal is commonly used for this purpose. Fifty sacks of charcoal are termed a load, which usually sells for about fifty shillings. The price for burning is three shillings per load, or twelve shillings for each cord of wood. The process of drying takes place, when the hop is taken off the kiln, and shovelled into the kiln chamber called the stowage-room; and in this place they are continually to be laid as they are taken off the kiln, till it may be thought convenient to put them into bags; which is rarely done till they have lain some time in the heap; for the hops, when first taken off the kiln, being very dry, would, if put into the bag at once, become too good a sample of hops to be used, they have lain some time in the heap; whereby they acquire a considerable portion of toughness, and an increase of weight.

6044. The bagging of hops is thus performed:—

6045. In the floor of the room, where the hops are laid to cool, there is a round hole or trap, equal in size to the mouth of a hop bag. After tying a handful of hops in each of the lower corners of a large bag, which serve afterwards for handles, the mouth of the bag is fixed securely to a strong hop, which is made to fit round the mouth of the bag itself being tied over in the same manner as a packer goes into it, when a person who attends for the purpose puts in the hops in small quantities, in order to give the packer an opportunity of packing and trampling them as hard as possible. When the hop is tied up, and the hops trampled in, in such a manner that it will hold the other packers, the hop, and hop packer, are lifted of by two hands having been previously formed in the corners in the manner mentioned above. The brightest and finest coloured hops are put into pockets or fine bagging, and the brown into coarse or heavy bagging. The former are chiefly used for brewing fine ales, and the latter for strong purposes. But while hops are thus preserved, it would be found, that where hops are tied in bags of too small a length of time, it is most proper to put them into coarse cloth. The proper length of a bag is two ells and a quarter, and of a pocket nearly the same, being one ells in width. The former, if the hops are good in quality, seldom weigh more than one hundred and fifty weight; but if the other, if of the Canterbury pochetting, about one hundred and a half. If the weight either exceeds or falls much
short of this medium, it induces a surmise, that the hops are either in themselves of an inferior quality, or have been injudiciously manufactured in some respect or other.

Although the subject of the present essay is not in the strictest sense one of botany, yet it is one in which a knowledge of the nature of the plant and of the ground on which it grows is of the highest importance. To it, more than to any thing else, is due the facility and certainty with which the crop is successfully grown.

6047. The stripping and stacking of the poles succeed to the operation of picking. It is of some consequence that this business be executed as soon as possible after the crop is removed; not only because the poles are, when set up in stacks, much safer from thieves, but because they are far less damaged by the weather than when dispersed about the ground with the vine on them. The usual price for stripping and stacking is five shillings per acre. At this time, such poles as may be deemed unfit for further service should be flung by, that the planter may have an early knowledge of the number of new poles which will be wanted; and thus the business of bringing on the poles may be completed in the winter time, when the horses are not required about other labour; and these new poles may be drawn from the wood on the ground, and adjusted to the separate stacks, as the state of the different parts of the ground may require, and the whole business finished before the poling season; whereas, when this method of flinging out the old poles is neglected at the stacking, the planter, being ignorant of the number of new poles that will be required for the ensuing year, often finds at the poling season that he has not laid in a sufficient stock.

6048. In performing the operation of stacking the poles are set up in somewhat conical piles, or congeries of from two hundred to five hundred each. The method of proceeding is this:—Three stout poles of equal length are bound together, a few feet from their tops, and their feet spread out, as those already mentioned for pointing the poles. These serve as a stay to the embry gone pile; the poles being dropped in on each side, between the feet of the first three, two or three at a time, cautiously keeping on the level, and so on till an even balance of the stability of the stack depends. The degree of inclination or slope, and the diameter of the base of the pile, vary with the length and the number of poles set up together. A stack of three or four hundred of these poles, of the environs of Maidstone, occupy a circle of near twenty feet in diameter. It is observable, however, that the feet of the poles do not form one entire ring; but are collected in bundles or distinct divisions, generally from three to six or eight in number; each fasciculus being bound tightly together, a few feet from the ground, with a large rough rope made of twisted vines, to prevent the wind from tearing away the poles. The openings between the divisions give passage to violent blasts, and tend to prevent the poles from being thrown down in a body; a circumstance which does not often take place in screened grounds; but, on the high exposure of Cox Heath, where great quantities of new poles brought from the Weald are piled for sale among the Maidstone planters, it is not uncommon for the piles to be blown down, and to crush in their fall the sheep or other animals that may have taken shelter under them. A caution this to the inexperienced in the business of stacking; and an apology, if one is wanted, for the minuteness of the detail.

6049. The operation of stripping is generally performed by women; being nothing more than tearing off the bind or vines. Many people burn it on the ground; others suffer it to be carried off by their workmen for firing; and there are some who tie it up into small bundles, which they bring home and form into a stack, to answer the purpose of barrows in heating their ovens or cowpers.

6050. The produce of the hop crop is liable to very considerable variation, according to soil and season, from two or three to so much as twenty hundred-weight; but from nine to ten, on middling soils, in tolerable seasons, are considered as average crops, and twelve or fourteen as good ones. Bannister asserts that sixty bushels of fresh-gathered hops, if fully ripe, and not injured by the fly or other accident, will, when dried and bagged, produce a hundred-weight. Where the hops are much eaten by the fleas, a disaster which often befalls them, the sample is not only reduced in value, but the weight diminished; so that, when this misfortune occurs, the planter experiences a two-fold loss.

6051. To judge of the quality of hops, as the chief virtue resides in the yellow powder contained in them, which is termed the condition, and is of an unctuous and clammy nature, the more or less clammy the sample appears to be, the value will be increased or diminished in the opinion of the buyer. To this may be added the colour, which it is of very material consequence for the planter to preserve as bright as possible, since the purchaser will always insist much on this article; though, perhaps, the brightest-coloured hops are not always the strongest flavoured.

6052. The duration of the hop plantation on good soil may be from fifteen to thirty years; but in general they begin to decline about the tenth year. Some advise that the plantation should then be destroyed, and a fresh one made elsewhere; others consider it the best plan to break up and plant a portion of new ground every two years, letting an equal quantity of the old be destroyed, as in this way a regular succession of good plantation will be kept up at a trifling charge.

6053. The expense of forming new hop-plantations is in general very great, being estimated, in many districts, at from not less than seventy to a hundred pounds the acre. The produce is very uncertain; or, at best, considerable; but in some seasons nothing nothing has been incurred. Where the lands are of proper sort for them, and there are hop-poles on the farm, and the farmer has a sufficient capital, it is probably a sort of husbandry that may be had recourse to with advantage; but under the contrary circumstances, hops will seldom answer. In growing them in connection with a farm, regard should be had to the extent that can be managed without detriment to the other tillage lands. On the whole, the hop is an expensive and precarious crop, the culture of which should be well considered before it is entered upon.
6054. The use of the hop in brewing is to prevent the beer from becoming sour.

6055. In domestic economy the young shoots are eaten early in the spring as asparagus, and are sold under the name of hop-tops. They are said to be diuretic; and taken in an infusion, to be good against the scurvy. The dried hop will arrive the wine as a florence flavor of the wine as a florence flavor in winter; for this purpose they must be gathered in autumn, soaked in water all winter; and in March, after being dried in a stove, they are dressed as flax. They require a longer time to rot than flax, and, if not completely made, will not serve the purpose. If the farmer who has a hop plantation need neither grow asparagus nor flax, and may, when the flowers fall from the vine, separate the fibre from the vine, and employ the poor, or machinery, in spinning and weaving it. A decoction of the roots of hops is considered as good a sudorific as sarsaparilla; and the smell of the flowers is found to be soporific. A pillow filled with hops was prescribed for the use of George III. in his illness of 1757.

6056. The hop is peculiarly liable to diseases. There is scarcely any sort of plant cultivated as a field-crop that is more liable to become diseased than the hop. It is, apt, in the very early stage of its growth, to be devoured, as it rises above the surface of the ground, by the ravages of an insect of the flea kind. At a more advanced stage, it is subject to the still more injurious effects of the green or long-winged fly, red spider, and otter moth: the first, by depositing their ova, afford the means of producing lice in great abundance, by which the plants are often very greatly, if not wholly, destroyed; and the larvae of the last prey upon the roots, and thus render the plants weak and subject to disease. The honey-dew is another disease to which the hop is exposed above the same time, and by which it is often much injured. The mould occurs in general at a somewhat later period, and is equally injurious. Hop-crops are also exposed to other injuries, as the blight and fire-blast; but which take place at different times, though mostly towards the later periods of the growth of the plants.

6057. The flea, which is said to be an insect of the same kind as which is so prejudicial to the young turnip, is observed to make the greatest havoc in seasons when the nights are cold and frosty, and the days very dry. The sweet tender tops of the young plants, which, though not wholly destroyed, shoot forth afterwards in a far less vigorous manner, and of course cannot compete in comfort with those which are exposed to diseases. It has been found to commit its depredations most frequently on the plants in grounds that have been doused the same year; on which account it has been suggested that the manure employed for the corn should be mixed with lime, and that it might be applied as directed above (6019); and that it should be applied either over the whole of the land, or only the hills, as seems more possible after the plants have been cut over; but the former practice is probably the best. It makes its appearance in the early, cold, spring months, and this is the time that its chief attacks are directed against it. At the beginning of the succeeding month, disappearing as the season becomes more mild and warm. In these cases, the principal remedy is that of having the land in a sufficient state of fertility, to enable the young plants to shoot up with such vigour and rapidity as to become quickly incapable of being fed upon and devoured by the insect. The frequent stirring of the mould about the roots of the plants with the hoe may be of utility in the same view.

6058. The green or long-winged fly is highly destructive to the young leaves of the plants, and mostly makes its appearance about the latter end of May, and in the two succeeding months; being supposed to be produced by the prevalence of north-easterly winds about that period. Under such a state of the wind, they are said to scarcely ever fail of covering the leaves; and by dropping their ova, of producing abundance of lice, which often much injure the crops; as when they have once obtained complete possession of the plants, they seldom or never leave them before they have wholly destroyed them. Insects of this sort generally attack the forwardest and most luxuriant hop-vines. Their removal chiefly depends upon the winds changing more to the south, and the setting in of more mild, warm, and temperate weather.

6059. In the case of the plants, the root of the plant, the roots, renders the leaves, and the branches attacked by the larvae, and the healthy growth of the hops is thereby greatly impaired, the crops being of course much more injured in their production. Stirring the earth well about the roots of the plants may probably sometimes be serviceable in cases of this kind.

6060. The honey-dew mostly occurs when the crops have been attacked by some of these kinds of insects, and when the weather is close, moist, and foggy. In these cases, a sweet clammy substance, which has the taste of honey, is produced upon the leaves of the plants, and they have at first a shining appearance, but soon afterwards become black. It is a disease that may be prevented by the more forward crops, and the chief dependence of the planter for its removal, according to Bannister, is that of heavy thinners showing taking place; as by this means, when the destruction of the hops has not proceeded too far, they are often much restored, the insects that devour the leaves and vines being greatly destroyed, the growth of vegetation being promoted, and a favourable harvest brought on the plants.

6061. The flea, mildew, or mildews, is a disease to which the crop is exposed at a later period of its growth, and which chiefly attacks the part where the hop is attached to the stem. It is said that its production is greatly promoted by damp clammy weather, and those crops that grow on low, close, and marshy grounds being most liable to be attacked by it: and it is found to soon spread itself over the whole crop, after it has once seized upon any part of it. The nature of this vegetable disease has not been yet sufficiently investigated by Whitewell and Wildenowe to be well understood; though it is known that there is a great deal of growing without light or change of air, attaching itself to plants already in a morbid condition, and by its roots penetrating their vessels; and on this supposition, the best remedy is believed to be thinning the plants, in order to afford a more free circulation of air, and admit the light more extensively, by which the vitality of the hops may be restored, and the disease be of course removed. In this view, it is probable, by planting the hills more thinly, and making them at greater distances from each other, the disease might in some measure be prevented from taking place. (See 6048)

6062. The fire-blast is a disease that hop-crops are exposed to in the later periods of their growth, and is generally supposed to proceed from the particular state of the air or weather. Others consider this disease as generally supposed more than the result of the attacks of the red spider. It has been conjectured to be the effect of lightning, as it takes place, for the most part, at these seasons when lightning is the most prevalent,
and in a very sudden manner: and besides the most forward and luxuriant vines are the most subject to be affected. It has been suggested, that in exposures where the crops are particularly liable to injury, it may be advisable to plant thinner, to keep back the growth of the plants as much as possible, by extirpating all the most forward shoots, and to employ a less proportion of the earthy compost in their culture.

6064. In respect to the duty on hops, it is best for the planter to have the acts before him. But every grower of hops in Britain is legally obliged to give notice to the excise, or on or before the first day of September, of the number of acres he has in cultivation, the situation and number of his oasts, and the place or places of bagging, which, with the store-rooms, or warehouses, in which the packages are intended to be lodged, are entered by the revenue officer. No hops can be removed from the rooms thus entered, before they have been weighed and marked by a revenue officer; who marks, or ought to mark, not only the weight, but the name and residence of the grower, upon each package.

Subsect. 2. Culture of the Coriander and Caraway. (fig. 804. a, b.)

6065. The coriander (Coriandrum sativum L., fig. 804. a) is a small-rooted annual, with branchy stems rising from one foot to one foot and a half in height. It is a native of the south of Europe, and appears to be naturalised in some parts of Essex, where it has been long cultivated. It flowers in June and July, and the seeds ripen in July and August.

6066. The culture and management of coriander consist in sowing it on a light rich soil in September, with seeds ripened the same year. Twenty pounds of seed will sow an acre. When the plants come up, thin them to six or eight inches' distance every way, and, next spring, stir the soil with a pronged hoe. In August the seed will be ripe, and if great care be not used, the largest and best part of it will be lost. To prevent this, women and children are employed to cut plant by plant, and to put them immediately into cloths, in which they are carried to some convenient part of the field, and there threshed on a sail-cloth. A few strokes of the flail get the seeds clean out, and the threshers are ready for another bundle in a few minutes. In Essex it is sometimes cultivated with caraway and teasel. (See Caraway.)

6067. The produce of coriander is from ten to fourteen cwt. on an acre. It is used by the distillers for flavouring spirits, by the confectioners for encrusting with sugar, and by the druggists for various purposes; for all of which it is said to have a ready sale.

6068. The caraway (Carum carvi, b) is a biennial plant with a taper root, like a parsnep, but much smaller, running deep into the ground. The stems rise from eighteen inches to two feet, with spreading branches and finely cut deep green leaves. It is a native of England, in rich meadows in Lincolnshire and other places, and has been long cultivated in Essex. It flowers in May and June, and the seeds ripen in autumn.

6069. The culture and management are the same as those of coriander. In all probability both plants would answer if sown like clover among a crop of corn; and hoed and thinned when the crop was removed, and again in the following spring. The method of sowing is the same as for coriander. Twenty pounds of seed will plough some old pasture land; if it has been pasture for a century the better; and the soil should be a very strong clayey loam. Twelve pounds of caraway seed are mixed with ten pounds of coriander, and twelve pounds of teasel seed: this is sufficient for one acre; and is sowed directly after the plough, harrowing the land well. When the plants appear of sufficient strength to bear the hoe, which will not be until about ten weeks after sowing, it must not be omitted; and in the course of the summer, the crop will require three hoeings, besides one at Michaelmas. The coriander being annual, will be fit to cut about the beginning of July. It is left in the field after cutting, and threshed on a cloth in the same manner as rape seed. About April following the caraway and teasel will want a good hoeing done deep and well; and another about the beginning of June. The caraway will be fit to cut in the beginning of July, and must be threshed in the same manner as the coriander. This common caraway is mostly sown on land, so strong as to require being a little exhausted to make it fit for corn. Caraway and coriander are often sown without teasel; the latter being troublesome and uncertain crop, and the produce of caraway much greater without it.

6070. The produce of caraway, on the very rich old leys in the hundreds or low lands of Essex, has often amounted to twenty cwt. an acre. There is always a demand for the seed in the London market.

6071. The uses of the caraway are the same as those of coriander, and its oil and other preparations are more used in medicine. Dr. Anderson says, both the roots and tops may be given to cattle in spring.

Subsect. 3. Plants which may be substituted for Brewery and Distillery Plants.

6072. As substitutes for hops, we may mention the common box (Buxus sempervirens), the leaves and twigs of which are said to be extensively used in all the beer brewed in Paris. The marsh trefoil (Menyanthes trifoliata) is much employed in Germany, and on the Continent generally; and, it is said, was formerly used in this country. One ounce of the dried leaves is considered equivalent to half a pound of hops. The plant is of easy culture in moist soil: all the plants of the same natural order, Gentianaee, and especially the different species of Gentiana, might be used in the same manner, more particularly the G. lutea, rubra, and purpurea. In Switzerland, a spirit is distilled from the roots of G. lutea. The dried roots of Geum urbanum, common in hedges, are sliced,
enclosed in a thin linen bag, and suspended in the beer cask, by the brewers of Germany, to prevent, it is said, the beer from turning sour, and to give it the colour of clove.

( Gard. Mag. vol. vi. p. 148.) In Sweden, Norway, and the north of Scotland, the heath (Erica L.) and common broom were, and still are, occasionally used as substitutes for the hop. In some parts of France and Germany notably, the clove is used in brewed beer.

In Guernsey the Triticum scorpius is used, and found to answer perfectly. In England, the different species of poppy and wormwood have been used for that purpose; and the foreign bitter, quassia, a tree of Guiana, is still used by the porter brewers. Whoever has good malt, therefore, or roots, or sugar, and understands how to make them into beer, need be at no loss for bitters to make it keep.

671. Carminative seeds, equal in strength to those of the caraway and coriander, are furnished by a very considerable number of native or hardy plants, and of flavours to which the drinkers of cordials and liqueurs are attached. Such are the fennels (Foeniculum) cultivated in Germany, parsley, myrrh, angelica, celery, carrot, parsnip, cow parsley, and many other umbelliferous plants; avoiding, however, the hemlock, fool's parsley, arnica, and some others which are poisonous. In Dantzic, where perhaps more seeds are used for flavouring spirits than any where else, several of the above and other plants are employed. Kimmel, their favourite flavour, is that of the cumin (Cuminum cyminum), an annual plant, a native of Egypt, and cultivated in the south of Europe; but too tender for field culture in this country. But caraway and fennel seeds are very generally mixed with cumin, or even substituted for it in distilling kimmel-wasser.

SECTION III. Oil Plants.

674. In Britain there are few plants grown solely for the production of oil; though oil is expressed from the seeds of several plants, grown for other purposes, as the flax, hemp, &c. Our chief oil plant is the rape.

675. Rape is the Brásica napus L.; Navalte, Fr.; Rübumen, Ger.; Rape silvatica, Ital.; and Napa silvestre, Span. It is a biennial plant of the turnip kind, but with a caulescent and woody fusiform root scarcely fit to be eaten. Von Thaer considers the French and Flemish colza (Kohlsaat, Ger.) a different plant from our rape: colza is more of the cabbage kind, and distinguished by its cylindrical root, cut leaves, and greater hardiness. Decandole seems to be of the same opinion.

676. Brásica campestris oleifera, according to these writers, is the colza or colza, or rape of the Continent, the most valuable plant to cultivate for oil; its produce being to that of the Brásica Napus, or British colza or rape, as 5 to 2. It is distinguished from the B. napus by the hispidity of its leaves. It would be desirable for agriculture, Decandole observes, that, in all countries, cultivators would examine whether the plant they rear is the B. campestris oleifera or the B. napus oleifera, which can easily be ascertained by observing whether the young plant is rough or smooth; if hispid, it is the B. campestris; if glabrous, the B. napus. Experiments made by Gaytouc show the produce of the first, compared with that of the second, to be as 9.5 to 7.00. (Hort. Trans. v. 23.)

677. For its leaves as food for sheep, and its seed for the oil-manufacturer, rape, or colza, has been cultivated from time immemorial. It is considered a native, flowers in May, and ripens its seeds in July. It may be sown broad-cast, or in rows, like the common turnip, or it may be transplanted like the Swedish turnip. The culture of rape for seed has been much objected to by some, on account of its supposed great exhaustion of the land; but where the soil and preparation are suitable, the after-culture properly attended to, and the straw and offal, instead of being burnt, as is the common practice, converted to the purposes of feeding and littering cattle, it may, in many instances, be the most proper and advantageous crop, that can be employed by the farmer.

678. The Calleys in Northumberland used to cultivate rape on thin clays, as a preparation for wheat, of which they had valuable crops afterwards. The land, in the early part of the season, was prepared as for fallow, and the rape sown in June or July, and eaten off by sheep in September or October; after which the soil was once ploughed for wheat. The rape may also be sown among a crop of drilled winter beans in May.

679. The soils best suited for rape are the deep, rich, dry, and kindly sorts; but, with plenty of manure and deep ploughing, it may be grown in others.

680. Young says, that upon fen and peat soils and bogs, and black petty low grounds, it thrives greatly, and especially on parred and burnt land, which is best suited to it; but it may be grown with perfect success on sandy, marshy, and other coarse waste lands, that have been ploughed up and properly prepared. As a first crop on such descriptions of land, it is often the best that can be employed. The author of The New Farmer's Calendar thinks that this plant is not perhaps worth attention on any but rich and deep soils; for instance, those luxuriant slips that are found by the sea-side, fens, or newly broken up grounds, where vast crops of it may be raised.

681. The preparation of old grass lands, if not parred and burned, need be nothing more than a deep ploughing and sufficient harrowing to bring the surface to a fine mould; and this operation should not be commenced in winter, because the grass and wire worm would have time to rise to the surface: but in February or March, immediately before sowing, or in July, or after the hay crop is removed, if the sowing is deferred till that season. When sown on old tillage lands, the preparation is precisely the same as that usually given for the common turnip: the land being ploughed over four or five times, according to its condition, as a fine state of pulverisation or thistle is requisite for the perfect growth of the crop. In this view, the first ploughing is mostly given in the autumn, that the soil may be exposed to the influence of the atmosphere till the early part of the spring, when it should be again turned over twice, at proper intervals of time; and towards the beginning and middle of June one or two additional ploughings should be performed upon it, in order that it may be in a fine mellow condition for the reception of the seed.
PRACTICE and, for the manner, whether in broad-cast or rows, the same.

8. The season for sowing rape is the same as that for the common turnip, and by its being taken off early, there is sufficient time allowed for getting the land in order for sowing wheat.

9. The season of transplanting begins as soon as the corn harvest as possible, being generally performed on the stubble of some description of corn crop.

10. The plants on the poorer soils may be left at six or eight inches apart or narrower, but on the rich they may stay twelve to nine inches with advantage to the seed. Few are likely to grow the plant on ridges with manure; but, if this were done, the same distance as for turnips will ensure a better crop of seed than if the plants were closer together. In close crops the seed is only found on the summits of the plants in wide crops on rich soils, it also covers their roots. When properly kept, no hoeing, thinning, or weeding, are necessary. Rape grown for seed will not be much injured by a very slight cropping from sheep early in the autumn, but considerably so by being eaten down in winter, or in the succeeding spring. The seed begins to ripen in the last week in June, and must then be protected from birds.

11. In harvesting rape great care is requisite not to lose the seed by shaking, chaffing, or exposure to high winds or rains.

12. Rape is reaped with the hook, and the principal point is to make good use of fine weather; for, as it must be gathered as fast as reaped, or at least without being housed or stacked like other crops, it requires a greater number of hands in proportion to the land, than any other plant. The reaping is very delicate work; for if the men are not careful, they will shed much of the seed. Moving it to the threshing-floor is attended with considerable loss of attention. One way is to make little waggons on four wheels with poles, and cloths strained over them; the diameter of the wheels being about two feet, and the cloth body five feet wide, six long, and two deep; these are drawn by one horse, and the whole expense is not more than 30l. or 40l. In large farms, several of these may be seen at work at a time in one field. The rape is lifted from the ground gently, dropped at once into these machines without any loss, and carried to the threshers, who keep hard at work, being supplied from the wagons as fast as they come, by one set of men, and their straw moved off the floor by another set. Many hands of all sorts being employed, a great breadth of land is finished in a short time. Some use also the method of bedding in the same way. All is liable to be stopped by rain, and the crop much damaged; it is, therefore, of very great consequence to employ as many people as possible, men, women, and boys, to make the greatest use of fine weather. The seed is likewise sometimes cleaned in threshing machines, but is generally put into sacks for the market. But when large quantities of seed are brought quickly together, as they are liable to heat and become mouldy, it may be a better method to spread them out thinly over a barn, granary, or other floor, and turn them as often as may be necessary.

13. The produce where the plant succeeds well, and the season is favourable for securing the seed, amounts to forty or fifty bushels or more on the acre. Marshal thinks, indeed, that on the whole it may be considered as one of the most profitable crops in husbandry. There have been, says he, instances, on cold, unproductive, old pasture-lands, in which the produce of the rape crop has been equal to the purchase value of the land. The seed is sold by the last of ten quarters, for the purpose of having oil expressed from it in mills constructed for that purpose. The price, like that of all crops of uncertain and irregular demand, is continually varying.

14. The uses to which the rape is applied are the following:

15. The use of the seed for crushing for oil is well known; it is also employed as food for tame birds, and sometimes it is sown by gardeners, in the same way as mustard and cress, for early salading.

16. The rape-cake and rape-dust, the former adhering masses of seed husks, after the oil has been expressed, either on the latter loose dressing, or as a dressing for cows of different kinds. They are reduced to powder by a malt mill or other grinding machine, and sometimes sown broad-cast over young clovers, wheats, &c., and at other times drilled along with turnip seed. Four hundred weight of powder sown with turnip seed will go over one acre in drills, but three times the quantity is required for all the same, at that distance. Experience has proved that this is a better measure on the following season. If rain happens to fall soon after the rape-dust is applied, the crop is generally abundant; but if no rain falls for a considerable period the effects of this manure are little discernible in the immediate crops, or on those which succeed it. There are turnip drills contrived so as to deposit the manure along with the seed.

17. The use of the haum to cattle in winter is very considerable. The stover (pods and points broken off in the threshing) as acceptable to cattle as the tops, are generally cut straw, and are at least better than wheat straw. When well get, the smaller stalks will be eaten up clean. The offal makes excellent litter for the farm-yard, and is useful for the bottoms of mows, stacks, &c. The haum of this plant is frequently burned; and, in some places, the ashes, which are equal to potash, are sold; by which practice, its manure is substituted, the soil must be greatly deteriorated. It is a custom in Lincolnshire,
sometimes to lay lands down with clole, under which the grass seeds are found to grow well. But this sort of crop, as already observed, is most suited to freshly broken-up or burned lands, or to succeed early peas, or such other green crops as are mowed for feeding cattle.

688. The rape as a green feed for sheep are scarcely surpassed by any other vegetable, in nutritious properties, and in being agreeable to the taste of the animals; but in quantity of produce, it is inferior to both turnips and cabbages. The crops are fed off occasionally from the beginning of November to the middle of April; being found of great value, in the first period, for fattening dry ewes, and all sorts of old sheep; and, in the latter, for supporting ewes and lambs. The sheep are folded upon them in the manner practised for turnips, in which way they are found to pay from 50. to 60., the acre; that quantity being sufficient for the support of ten sheep, for ten or twelve weeks, or longer, according to circumstances. Rape has been found, by experience, to be superior to turnips in fattening sheep, and in some cases, even to be apt to destroy them by its fattening quality. In The Corrected Report of Lincolnshire it is likewise observed, that rape grows on fresh land has the stem as brittle as glass, and is superior to every other kind of food in fattening sheep; while that produced on old tillage land has the stem tough and wiry, and containing comparatively little nourishment.

690. The Sâsânum orientale (Sesame, Fr.; Êsémo, Ital.); Bigmonnâceæ, is cultivated in Italy for its seeds, which are eaten roasted like those of maize, boiled like those of the millet, made into a coarse flour like those of the beeck or buck wheat, but principally bruised for an oil used as a substitute for butter.

690. Among other plants which may be cultivated by the British farmer as oil plants, may be mentioned all the species of the Bràssica family, the Sinapis or mustard family, and the Râphænus or radish family, with many others of the natural order of Cruciferae. The seeds of these plants, when they remain too long on the seedsman's hands for growing, are sold either for crushing for oil, or grinding with mustard seed. This includes a good deal of wild charlock and wild mustard seed, which is separated in the process of cleaning grain by the farmers among whose corn these plants abound, and sold to the seed agents, who dispose of it to the oil or mustard millers. Various other Cruciferae, as the Myâgrum sativum, Râphænus chinensis var. ëlèifer, both cultivated in Germany, the Lysînnum, Sîsînum officinale, Turritis, &c., might also be cultivated for both purposes.

600. The small or field poppy (Papaver Rhoëas; Oliette, Fr.), and also the Maw seed (P. somniferum, var. Pavot, Fr.), a variety of the garden poppy, are, as we have seen (467.), cultivated on the Continent as oil plants; the oil being esteemed in domestic economy next to that of the olive. Other species might be grown for the same purpose. All of them being annual plants require only to be sown on fine rich land in April; thinned out to six or eight inches' distance when they come up, according to the species; kept clear of weeds till they begin to run; and to have their capsules as they ripen gathered by hand and dried in the sun.

610. The sunflower (Helianthus ânnus; Turnesol, Fr.; and Girasole, Ital.) has been cultivated in Germany for its seeds, which are found to yield a good table oil; its husks are nourishing food for cattle.

*610. The Aârachis hypogæa, Myâgrum sativum, Hâpersis matronsâtis, Râphænus salius ëlèifer, and Ricciâus commânus are cultivated in France as oil plants.

Sect. IV. Plants used in Domestic Economy.

610. Among agricultural plants used in domestic economy, we include the Mustard, Buck-wheat or Beech-wheat, Cress, Tobacco, Chicory, and a few others; with the exception of the first, they are grown to a very small extent in Britain, and therefore our account of them shall be proportionately concise.

610. There are two species of mustard in the cultivation, in the fields, the white mustard (Sinâpis âlba, fig. 805. a), and the black or common (Sinâpis nigra, b). Both are annuals, natives of Britain and most parts of Europe, and cultivated there and in China, for an unknown period. White mustard flowers in June, and ripens its seeds in July. Black mustard is rather earlier. Mustard is an exhausting crop, but profitable when the soil answers, and especially in breaking up rich loamy lands, as it comes off earlier, and allows time for preparing the soil for wheat. In breaking up very rich grass lands, three or four crops are sometimes taken in succession. It cannot, however, be considered as a good general crop for the farmer, even if there were a demand for it, as, like most of the commercial plants, it yields little or no manure. The culture of black or common mustard is by far the most extensive, and is chiefly carried on in the county of Durham. The seed of the black mustard, like that of the wild sort and also of the wild radish, if below the depth of three or four inches, will remain in the ground for ages without germinating; hence, when once introduced it is
difficult to extirpate. Whenever they throw the earth out of their ditches in the Isle of Ely, the bank comes up thick with mustard; and the seed, falling into the water and sinking to the bottom, will remain embalmed in the mud for ages without vegetation.

6104. No such luxury as mustard, in its present form, was known at our tables previously to 1720. At that time the seed was onlycuriously separated in a mortar, as coarsely divided from the integuments, and in that rough state prepared for use. In the year I have mentioned, it occurred to an old woman of the name of Clements, resident at Durham, to grind the seed in a mill, and to pass the meal through the several processes which are resorted to in making flour from wheat. The secret she kept for many years came to herself, and, in the period of her exclusive possession of it, supplied the principal parts of the kingdom, and in particular the metropolis, with this article; and George I. stamped it with fashion by his approval. Mrs. Clements as regularly twice a year travelled to London, and to the principal towns throughout England, for orders, as any tradesman's riper of the present day; and the old lady contrived to pick up not only a decent pittance, but what was then thought a tolerable competence. From this woman's residing at Durham, it acquired the name of Durham mustard. (Mech. Mag. vol. iv. p. 67.)

6105. Any rich loamy soil will raise a crop of mustard, and no other preparation is required than that of a good deep ploughing and harrowing sufficient to raise a mould on the surface. The seeds may be sown broadcast at the rate of one hoppel per acre; harrowed in and guarded from birds till it comes up, and hoed and weeded before it begins to shoot. In Kent, according to the survey of Boys, white mustard is cultivated for the use of the seedsmen in London. In the tillage for it, the ploughed land is, he says, harrowed over, and then furrows are stricken about eleven or twelve inches apart, sowing the seed in the proportion of two or three gallons per acre in March. The crop is afterwards hoed and kept free from weeds.

6106. Mustard is reaped in the beginning of September, being tied in sheaves, and left three or four days on the stubble. It is then stacked in the field. It is remarked that rain damages it. A good crop is three or four quarters an acre; the price from 7s. to 20s. a bushel. Three or four crops are sometimes taken running, but this must in most cases be bad husbandry.

6107. The use of the white mustard is or should be chiefly for medical and horticultural purposes, though it is often ground into flour, and mixed with the black, which is much stronger, and far more difficult to free from its black husks. The black or common mustard is exclusively used for grinding into flour of mustard, and the black husk is separated by very delicate machinery.

6108. The French either do not attempt to separate the husk, or do not succeed in it, as their mustard when brought to table is always thick and fibrous. It is, however, more pungent than ours, because that quality resides chiefly in the husk. The constituents of mustard seed appear to be chiefly starch, mucus, a bland fixed oil, an acrid volatile oil, and an ammoniacal salt. The fresh powder, Dr. Cullen observes, shows little pungency; but when it has been moistened with vinegar and kept for a day, the essential oil is evolved, and it is then much more acrid.

6109. The leaves of the mustard family, like those of all the radish and Brassicae tribe, are eaten green by cattle and sheep, and may be used as pot-herbs. The hauml is commonly burned; but is better employed as litter for the straw-yard, or for covering underdrains, if any happen to be forming at the time.

6110. As substitutes for either the black or common mustard, most of the Cruciferae enumerated when treating of oil plants (6095.) may be used, especially the Sinapis arvensis, or charlock, S. orientalis, chinensis, and brassicae, the latter commonly cultivated in China. The Raphanus Raphanistrum, common in corn fields, and known as the wild mustard, is so complete a substitute, that it is often separated from the refuse corn and sold as Durham mustard seed.

SUBSET. 2. Buck-wheat. — Polygonum Fagopyrum L.; Octandria Trigyna L., and Polygymoe J. Blé noir or Blé Sarrasin, Fr. (corrupted from Had-razin, i.e. red corn, Celtic); Bachwitenzen, Ger.; Miglio, Ital.; and Trigo negro, Span. (fig. 806.)

*6111. The buck-wheat, or more properly beech-wheat (from the resemblance of the seeds to beech mast, as its Latin and German names import), is an annual fibrous-rooted plant, with upright flexuous leafy stems, generally tinged with red, and rising from a foot to three feet in height. The flowers are either white or tinged with red, and make a handsome appearance in July, and the seeds ripe in August and September. Its native country is unknown; though it is attributed to Asia. It is cultivated in China and other countries of the East as a bread corn, and has been grown from time immemorial in Britain, and most parts of Europe, as food for poultry and horses, and also to be ground into meal for domestic purposes. The universality of its culture is evidently owing to the little labour it requires: it will grow on the poorest soil, and produce a crop in the course of three or four months. It was cultivated as early as Gerard's time (1597), to be ploughed in as manure: but at present, from its inferior value as a grain, and its yielding very little hauml for fodder or manure, it is seldom grown but by gentlemen in their plantations to encourage game. Arthur Young, however, "recommends farmers in general to try this crop. Nineteen parishes out of twenty, through the kingdom, know it only by name. It has
BUCK-WHEAT. numerous excellencies, perhaps as many to good farmers, as any other grain or pulse in use. It is of an enriching nature, having the quality of preparing for wheat, or any other crop. One bushel sows an acre of land well, which is but a fourth of the expense of seed-barley. Its principal value is not so much in the crop as in the great good it does the land by shading it from the heat of the sun. When the wheat fallow can be perfectly cleaned before the middle of June, it is far better to sow the ground with buck-wheat than let it be bare; the wheat crop, whether the dung be laid on before or after the buck-wheat, will be one tenth better than without it. (J. M.)

6112. There are different species in cultivation, and P. tataricum (fig. 807, a.) is said by some to be nearly as productive as P. Fagopyrum. Von Tschirnhaus, however, is of a different opinion. In Nipal P. emarginatum (b) is cultivated. According to M. Decandolle, the farmers of Piedmont, especially in the vicinity of Luzerne, chiefly employ the P. tataricum; because it ripens more quickly, and is therefore less likely to suffer from cold summers, or frosts, and on the sides of the mountains. The Piedmontese distinguish the P. Fagopyrum by the name of "Formentine de Savoie," and the P. tataricum by that of "granette," and "Formentine de Luzerne." The principal objection to the latter is, that its flowers expand irregularly and unequally, and that the flour is blackish and rather bitter. The P. Fagopyrum is, however, cultivated in the richest parts of Europe as a food for domestic fowls or other birds, rather than for the use of man. Cakes made of the flour of this species, we are told by Thunberg, round, coloured, and baked in an urn in every inn in Japan. Loureiro states, that P. odoratum is cultivated throughout the kingdom of Cochin China, as an excellent vegetable for eating with broiled meat and fish. (Bot. Reg.)

6113. In the culture of the buck-wheat the soil may be prepared in different ways, according to the intention of the future crop; and for this there is time till the end of May, if seed is the object, and till June if it is to be ploughed in. It will grow on any soil, but will only produce a good crop on one that is tolerably rich. It is considered one of the best crops to sow along with grass seed; and yet (however inconsistent) Arthur Young endeavours to prove that buck-wheat, from the closeness of its growth at the top, smother and destroys weeds, whilst clover and grass-seeds receive considerable benefit by the shade it affords them from the piercing heat of the sun!!

6114. The season of sowing cannot be considered earlier than the last week of April or first of May, as the young plants are very apt to be destroyed by frost. The mode is always broad-cast, and the quantity of seed a bushel per acre; it is harrowed in, and requires no other culture than pulling out the larger weeds, and guarding from birds till the reaping season.

6115. Buck-wheat is harvested by mowing in the manner of barley. After it is mown, it must lie several days, till the stalks are withered, before it is housed. It is in no danger of the seeds falling, nor does it suffer much by wet. From its great succulence it is liable to heat, on which account it is better to put it in small stacks of five or six loads each, than in either a large one or a barn.

6116. The produce of the grain of this plant, though it has been known to yield seven quarters an acre, may be stated upon the average at between three and four; it would be considerably more did all the grains ripen together, but that never appears to be the case, as some parts of the same plant will be in flower, whilst others have perfected their seed.

6117. The use of the grain of buck-wheat in this country is almost entirely for feeding poultry, pigeons, and swine. It may also be given to horses, which are said to thrive well on it; but the author of The New Farmer's Calendar says, he thinks he has seen it produce a stupefying effect.

6118. It has been used in the distillery in England; and it is a good deal used in that way, and also as horse-corn, on the Continent. Young says, a bushel goes farther than two bushels of oats; and mixed with at least four times as much bran, will be full feed for any horse for a week. Your bushel of buck-wheat, put up at least will fatten a hog of sixteen or twenty stone in three weeks, giving him afterwards three bushels of Indian corn or hog-peas broken in a mill, with plenty of water. Eight bushels of buck-wheat meal will go as far as twelve bushels of barley meal.

6119. The meal of buck-wheat is made into thin cakes called crumpets in Italy, and even in some parts of England; and it is supposed to be nutritious, and not apt to turn acid upon the stomach. (Withering.)

6120. The blossoms of this plant afford a rich repast to bees, both from the quantity of honey they contain, and from their long duration. On this account it is much prized in France and Germany; and Du Hamel advises bee farmers to carry their hives to fields of this crop in the autumn, as well as to heath lands.

3 (i) 1
The haumin of buck-wheat is said to be more nourishing than clover when eaten while in flower. Buck-wheat is well suited for a peculiar kind of bread, baked in cakes, and, in consequence, is a great favorite, as it comes home in such a state of intoxication as to be unable to walk without reeling. The dried haumin is not eaten readily by any description of animal, and affords but very little manure. On the whole, the crop is of most value when ploughed in green for the latter purpose.

As a seed crop, the author of The New Farmer's Calendar seems justified in saying, it is only valuable on land that will grow nothing else.

Subsect. 3. Tobacco.—Nicotiana L.; Pentaudria Monogynia L., and Solanace J. Le Tabac, Fr.; der Tabak, Ger.; Tobacco, Ital.; Tabaco, Span.; and Peumon or Petunio, Brasil.

The species cultivated are annuals, natives of Mexico, or other parts of America, and, according to some, of both hemispheres. It was brought to Europe early in the sixteenth century, after the discovery of America by Columbus, probably about 1519, from Portugal to France about 1550, by John Nicot, after whom the plant is named; and to England, according to Lohol, about 1570; according to Hume by Ralph Lane, in 1586, from the island of Tobacco in the Gulf of Mexico, whence the popular name.

The custom of smoking is of unknown antiquity in Asia, Persia, and other eastern countries; but whether the plant used was tobacco is very doubtful. The natives of Mexico, in the present century, not only use it as an article of luxury, but as a remedy for all diseases, and, when provisions fail them, for allaying the pains of hunger and thirst. The use of smoking was introduced to England by Capt. Lane, who had learned the custom in Virginia, in 1565. He brought it home with him, and over the house of the custom to Sir Walter Raleigh, who soon acquired a taste for it, and began to teach it to his friends. He gave, we are told, "smoking parties" at his house at Islington, when the guests were treated with hothouse curtains and hung with white drapery. Down to the time of Elizabeth, it was not uncommon for ladies to smoke. During the reign of James I., smoking, like most of the pleasures of Europe, violently opposed its use. James of England wrote a book against it; the Grand Duke of Moscow forbade its entrance into his territory under pain of the knout for the first offence, and death for the next. The custom took root in England, and, like many similar prohibitions, all of which were as ridiculous as those which attended the introduction of coffee, or Jesuit's bark. At present, all the sovereigns of Europe, and most of those other parts of the world, derive a considerable part of their revenue from tobacco.

The cultivation of tobacco on the Continent was not attempted, except in gardens, till the beginning of the seventeenth century. Under Louis XIII. and XIV., its cultivation was allowed in certain provinces of France; and about the same time it was introduced as an article of cottage or spade culture, in Holland, Germany, and parts of Switzerland. It also spread into Switzerland and Italy, and to various countries of the East. It is at present cultivated in almost every country of the world, but for commercial purposes chiefly on the Continent and islands of North America, and more especially in Virginia, Cuba, and Brazil. In no other parts of the world is it so well manufactured for the purpose of smoking as in Havana.

In England the practice of planting and growing tobacco began to creep in in the time of Charles I., and an act was passed fixing a penalty of 10s. for every rod of land so cultivated, but making it lawful, "to the exceeding of great small quantities, not exceeding to the value of a piece of common ware," or in any private garden for physic or chirurgery. This act and others were confirmed by different acts during the reign of Geo. III. Notwithstanding this act, however, tobacco was much cultivated a few years prior to 1752, in the vale of York and Ryedale. In the latter district it did not come under the notice of the royal authority; and was cured and manufactured by a man who had formerly been employed upon the tobacco plantations in America; who not only cured it properly, but gave it the proper cut, and finally pressed it for the pipe. But in the vale of York the cultivators of it met with less favourable circumstances. Their tobacco was purchased on contract, and themselves allowed of nothing but what was said, were paid to the amount of 30s. per hundredweight. This was enough to put a stop to the illegal cultivation of tobacco. But, perhaps rather unfortunately, it has likewise put a stop to the cultivation of that limited quantity of half a rood, which the law allows to be planted for the purpose of physic and chirurgery, or destroying insects.

In Scotland, about the same time, tobacco was cultivated in various parts, more especially in the neighbour of Kelso and Jedburgh. Its produce was so great, that thirteen acres at Craigs fetched 16l. at the low rate of 10s. per lb. (under 2s. per acre), and 97 per lb. for the best. At this time, as much, had not an act of parliament obliged the cultivator to dispose of it to government at that price. (County Reports.)

In Ireland, tobacco was introduced into the county of Cork, with the potato, by Sir Walter Raleigh; but the culture of the former does not appear to have made much progress, though, according to Humboldt, it is said to have been cultivated in England more than one hundred and twenty years, having been extensively cultivated in Portugal at the time that Sir Walter Raleigh brought it from Virginia to England in 1585. A writer in 1725, quoted by Brodigan, says, I have not heard that a rood of tobacco was ever planted in this kingdom. An act of George III. repealed several preceding acts, that prohibited the production and trade of tobacco in Ireland; and this is the foundation on which Ireland now rests her claim to the culture of this plant. Brodigan says: In the year 1785, the yearly amount of tobacco, which that year there were one hundred and thirty acres under tobacco; and in 1829, one thousand acres in Wexford alone. "It has been partially cultivated in the adjoining counties of Carlow, Waterford, and Kilkeny, but with little success. The cultivation was made in the vicinity of Westport. It has been grown in one or two instances near Dublin; in the northern section of the kingdom two or three trials have taken place on a small scale;" and Mr. Brodigan, the author of the treatise from which we quote, has cultivated several acres in the neighbourhood of Drogheda, preparing the soil by horse labour as for turnips.

The restrictive system will probably, at no distant time, be removed from tobacco, and from every other crop; but that tobacco ever will enter into the general course of crops of the British farmer, we do not think likely; because, when traded in, as in every thing else, is once made free, the tobacco of warmer climates will unquestionably be preferred to that of the British isles. At present there is a number of gentlemen in the House of Commons who use tobacco; but should its use become unfashionable, or public health, we may be sure be an attempt made to lay such a tax on the foreign commodity as would give the landed interest a monopoly over articles on which no duties can be forced by the rich on the poor. We trust, however, to the growing political sense of the country, to the force of opinion, in short, to the press, to avert such an evil. In the mean time, we ardently desire to see the cultivation of tobacco permitted and encouraged, in order that the British population of that country; and we should wish also to see every cottager in the three kingdoms growing his half rood, which the law permits, and which, at a moderate calculation, ought to produce 4 lbs. of tobacco from each. In smoking or selling it, or for selling to his neighbours, for this purpose we shall enter into the culture of tobacco at greater length than might otherwise be advisable.
6130. *The annual species of tobacco*, like the annual species of almost all dicotyledonous plants, may be grown in every country and climate; because every country has a summer, and that is the season of life for annual plants. In hot, dry, and short summers, like those of the north of Russia and Sweden, tobacco plants will not attain a large size, but the tobacco produced will be of delicate quality and good flavour: in long, moist, and not very warm summers, such as those of Ireland, the plants will attain a very large size, perhaps as much so as in Virginia, but the tobacco produced will not have that superior flavour, which can only be given by abundance of clear sunshine, and free dry air. By a skilful manufacture, and probably by mixing the tobacco of cold countries with that of hot countries, by using different species, and perhaps by selecting particular varieties of the Virginian species, the defects in flavour arising from climate may, it is likely, be greatly remedied.

6131. *Species and varieties*. The species almost every where cultivated in America is the *N. Tabacum* (fig. 808), or Virginian tobacco, of which there is a variety or sub-species known as *N. macrophyla*, but of which we have never seen any plants. *N. réstica* is very generally cultivated almost to the exclusion of the other species in the north of Germany, Russia, and Sweden, where almost every cottager grows his own tobacco for smoking. It also seems to be the principal sort grown in Ireland. There is a variety of it cultivated in Wexford, erroneously denominated Orénooko, and another commonly called negro-head. Both are very hardy and very productive, but the produce is not of a very good flavour. There are other species grown in America; the best Havana cigars are said to be made from the leaves of *N. répanda* (fig. 810, a), a species introduced to this country from Havana in 1812. The Indians of the Rocky Mountains of North America are said to prepare their tobacco from *N. quadrivalvis* (fig. 810, b), introduced in 1811, and *N. mána* (fig. 810, c) introduced in 1822. These species are all annuals, and the last requires the protection of a greenhouse to make it ripen its seeds. There are several very distinct varieties, if not species, cultivated in the Caracas, of which some account by Mr. Fanning, proprietor of the Botanic Garden of the Caracas, will be found in the Gardener's Magazine, vol. vi. p. 327. There are also some other annual species, and some species of the genus *Petunia* which is nearly allied to the *Nicótina*, the leaves of which might be manufactured into very good tobacco. There can be little doubt that the *N. Tabacum*, the seeds of which may be purchased in every seed-shop, is alone deserving the attention of the British cultivator, as a first experiment.

6132. *Soil*. In a strict sense, the native soil of the tobacco is unknown in this country; by which we mean the primitive earths or rocks to which it belongs. We are inclined to attribute it to alluvium and sand-stone rather than to clay or lime. In
Virginia the best tobacco is grown in a rich loamy, but rather light soil, which has been newly taken into cultivation. In Alsace, where we have seen stronger tobacco of the Virginian kind than in any other part of France or in Germany, the soil is a brown loam, rather light than heavy, such as would grow excellent potatoes and turnips, and which has been for an unknown period under the plough. Wherever potatoes or turnips may be cultivated, there we think tobacco may be grown.

6133. Climate. As it is beyond a doubt that the best tobacco is produced in countries within the tropics, it is evident that it cannot be worth culture in Britain in situations not naturally mild or warm. Tobacco can never be worth growing in situations much above the level of the sea, nor on wet springy soils or northern exposures.

6134. Culture. We shall notice in succession the practice in the West Indies, Virginia, and Maryland, in Alsatia, in Holland, in the South of France, and in Ireland, as lately practised by Mr. Brodigan, and suggest what we think the best mode. We shall draw our information chiefly from a valuable article in the Nouveau Cours Complet d' Agriculture, edition 1823, and from the treatise of T. Brodigan, Esq., 1830; looking into Carver's Treatise on the Tobacco Plant, 1779; Tatham's Historical and Practical Essay, 1800; Jennings's Practical Treatise, 1830; and our own notes of 1815-18, 19, and 1828, on Sweden, Germany, and France.

615. Culture in the West Indies. In the island of Tobago, the tobacco seeds are sown in beds twelve feet square, and transplanted into the fields when about the size of young lettuces, in rows three feet apart, and the plants are forced to feet distant from each other. The rows are thinned when about a foot and a half high. The buds which push from the axil of the leaves are taken out before many of them are found to have flowers, or before they become oblong; the seedpods begin to open at this time, and the seeds are taken out and sown in the bed for transplanting. The plants are thinned and transplanted to a fathom, and the spaces between them are kept free to be used for other plants. The stems are thinned out to one plant per foot, and the soil is thrown over the stumps when they have been cut down. They are thinned each year when they stand about three feet high, and completely excluded from air for a month. They are now taken out and tied into bundles, of about sixty leaves in each, which bundles are kept completely excluded from the air in a box or chest till wanted for disposal to the manufacturer. (Dr. Barbara's contemporary of Sir H. Leveson, quoted by Brodigan, p. 121.)

615. Culture in Virginia and Maryland. New soil of a medium quality is preferred; the seeds are mostly produced by the owners of the land, some finely prepared chalk, or finely prepared earth, as early in spring as possible, and covered with straw, branches, or boards at nights when any danger is apprehended from frosts; they are of course kept clear of weeds. The field intended for the plants is in the meadow time well laboured with the plough; it is then dug to a depth of nine inches, and ridged out to the depth of a yard marked with knots, at three feet apart; the plants of the one row being alternated with the intervals of the other; so that when the field is completed, the whole stand in quincunx. The plants are taken from the seed-bed to the field when they have five or six leaves, but not before. After the plants are six inches high, they are thinned, with four or five plants on an inch, and transplanted in cloudy weather. They are taken up carefully, raising the earth under them with a spade, and carrying them to the field in a basket, and they are planted with dibbers in an inch diameter and fifteen inches long. They are inserted as deep as the seed leaf, but no deeper. In a month afterwards they will have grown a foot in height, and will require to be hoed and weeded. When they have attained the height of two feet, the summit of each plant is pinched out, and the lower small leaves, and any others dirtied or injured by pests, are pinched off. From eight to twelve good leaves may now remain on each plant. Planting appears to affect the size and shape of the leaves; none appearing in the joints or axil of the leaves. From the time that the tops of the plants are pinched off, till that when the crop is fit to be gathered, is generally about five or six weeks. During this time the plants are thinned out to four or five leaves three to four times a week, for the purpose of thinning out the thinnings, and to prevent the whole leaf from being pinched off. This will also tend to prevent the loss of the crop, thus confine the entire effort of vegetation to the nourishing of the eight or twelve leaves. When the leaves begin to change colour, droop at the extremities, begin to smell rather more strongly, to become furrowed at the touch, and easily broken when bent, the plants are cut over by the surface of the ground, and all the leaves which are cut off are kept in an unheated shed, and others an inch above it. Each plant is left on the spot where it is cut for one day, and turned in the course of that day three or four times, to expose every part equally to get dried by the heat of the sun. Sometimes the plants are gathered into heaps, and remain on the field during the night in order to be spread out again the next day; but more generally they are collected together before the dew begins to fall, and put into a bin covered with boards on which are laid, and left in that situation, excluded from the air, for three or four days to ferment. Afterwards they are taken out, and two or three tied together at the root end of the stem, or the same height, and will require to be hoed and weeded. When these are hoed, they hang across lines or cross-beans, and thus dried in open sheds. After the plants have been completely dried, they are taken down from the cords, poles, or beams, to which they have been attached, in a moist day; because if they were to be handled in a very dry day, the leaves would crumble to powder, and the tobacco would be injured. The leaves are tied with mats for a week or two to sweat; during this time the leaf is frequently examined and turned, in order that every part may be equally heated and fermented, and no part burnit. This is said to be the most important operation of the whole, and is unquestionable what the leaves are to be cut, they are placed in mats, which can teach its attainment. The fermentation being completed, the leaves are separated from the stems, the latter thrown away, and the former separated into three classes, bottom leaves, top leaves, and middle leaves. These leaves are now dried under cover, and tied together in bundles of ten or twenty leaves, which are compressed so as to exclude all air by means of a round board of the same diameter as the interior of the cask, and which is every now and then put in and pressed down by means of a lever, which communicates a pressure of between 300 and 400 pounds. This lever is placed in the middle of close piles of twelve inches high. The operation is always performed when the air is humid, because, as before observed, dried tobacco is extremely brittle. Good tobacco thus prepared no longer ferments, except very slightly in the succeeding spring or summer, and which is found to be an advantage. The first tobacco is grown in the west of Virginia and Maryland, near the Alleghany Mountains, where the temperature, during its growing season, is between 60° and 70°. (N. Cours Complet d'Agr., 1833.) The species of this case is unquestionably N. Tabacum.

615. Culture of the tobacco in India. The species is chiefly N. Tabacum; a plant sometimes grown in the east of Virginia and Maryland, near the Alleghany Mountains, where the temperature, during its growing season, is between 60° and 70°. The seed is sown in hotheds, ten feet broad, and of any convenient length; the depth of the dung of the bed is two feet deep, and the frame which is placed on it is sometimes covered with sashes, but more commonly with mats only during nights. The plants are transplanted into fields which receive a sort of garden culture.
TOBACCO.

The surface is laid out into beds or ridges two feet and a half wide, with alleys of nine inches of earth, one hundred and thirty-two feet long, and of the same width as the row of rich soil and dung rotten almost to mould. The direction of the bed is north and south, and on each two to three rows of plants are inserted at eighteen inches' distance between the rows, and at the same between plant and plant; thus the plants are obliged to gather all the benefits of the other during the summer culture is the same as in Virginia, but the gathering of the crop is differently performed. When the leaves have reached the usual symptoms of maturity, the lowest, or those of the third quality, and the middle leaves, or those of the second quality, are stripped off and kept separate, and from four to six at top left on for some time longer are left on the plant, and in the meantime the bottom leaves, or of a sucker or bud which makes its appearance pinched off. The top leaves, or those of the first quality, are gathered when ready; and all the remaining parts of the process with the three qualities is exactly the same as in Virginia. (Ibid.)

618. Culture in Asia, and generally in the north and west of France and south of Germany. The seed, chiefly of N. Tabacum, is sown in March, or even earlier, in beds of fine mould in a garden, covered at night, and thinned to one plant a yard day also, with straw mats. When it begins to come up, these are removed by nine o'clock in the morning: but on again when it has come up, and the stalks have produced their seed leaves, the straw mats are supported by hoops or rods, so as not to injure the plants. About the end of April, the plants will be found to have attained from two to four leaves, exclusive of their seed leaves, and these are considered the season for transplanting them into the fields. The best crops, other circumstances the same, are obtained from plants transplanted before the middle of May. Both in Holland and Alsace, sheep's dung is found the best manure for the tobacco. The ground is made as fine as possible, not laid into ridges unless wet, and the plants are planted in rows, generally two feet and a half apart, and the plants alternating at the same distance in the row. Much of the value of the crop depends on the dryness and warmth of the summer, a good wine year being invariably a good tobacco year. In cold wet seasons many of the lower leaves become badly injured or the top one only, but all generally become obvious by changing into holes after the last drying; their inferiority then becomes obvious to the purchaser. The top leaves alone are those used for manufacturing into snuff, and they become injured by the weather as generally remain on the plant till the last, but the lower leaves are commonly gathered by the fifteenth of July. The tops of the plants are not generally pinched off till about the beginning of August, and they continue gathering leaves from that time till the end of September. If, at eight days after the operation of topping, the side buds are pinched off. After the leaves are gathered, they are laid on the ground in bunks or heaps, according to their qualities; and when they are taken to the drying sheds, they are again separated and picked, and all those of one quality threaded together on lines, leaving a space about the width of a finger between each leaf. The dried plants are stretched from one to the other, and then placed to dry lengthwise under the covers of cottage roofs, which are made to project from one foot to three feet for the purpose of drying tobacco and maize. The more extensive growers have large sheds or barns on purpose, and the floors are covered with earth or sand all sides, so as to be left free for the ventilation. When the air does not circulate freely among the leaves, instead of drying yellow they dry green or black, lose their graceful colour, and the midribs become rotten, and the whole leaf falls to pieces.

Leaves which on the plant were most exposed to the sun and dew, such as the top leaves, always dry to the leaves. The leaves remaining on the plant till the harvest is become dry; but the lower leaves are generally gathered by the fifteenth of July. November or December, though some of the leaves of inferior qualities are frequently purchased for the manufacture of smoking tobacco in the month of October. But these must be immediately manufactured, otherwise they become dead and tough. The leaves are then laid in heaps as a bad line day, and the leaves are not taken off the threads, but they are laid down in a humidi mild day on a dry airy floor, one above another, the depth of from fourteen inches to half a foot. Here they lie for some time, and are examined occasionally, and when they are not heating, or if they heat, they are immediately hung up again; if they do not, they remain in that position until purchased by the manufacturer. Often, indeed, they are manufactured as soon as properly dried on the strings. (Ibid.)

619. The culture of tobacco in the south of France is not materially different from what it is on the shores of the East, and the tobacco of the south of France is naturally of a better quality; but the care taken of it by the cultivators, especially in the drying and fermenting, being less than in less favourable climates, the quality becomes reduced, so that the tobacco of Alsace is preferred to that of Garonne. The tobacco of Florence in Virginia, and that of Florence in Virginia, are manufactured into snuff, as are those on the strings or beams. Being thoroughly dried, the leaves are separated, tied up in hands, and laid in heaps to ferment. These heaps are placed on boarded floors raised three or four inches above the surface of the soil; they are made two feet broad and two feet high, the width requiring exactly two hands, half of the one heap to the space of the ends of the leaves footstall. This operation is commonly performed between the fifteenth of November and the fifteenth of January, and the tobacco remains in that state till it is purchased by the manufacturer. The manufacturer having agitation up the head of the tobacco, and balls of three hundred, is divided by the ridges, the hogsheads, the trunks, the leaves, the classes according to their qualities, and finally puts them in hogheads, packing them closely by means of pressers. In these hogheads the tobacco remains till taken out to be made into snuff, cigars, or common smoking tobacco.

620. The culture of tobacco in Ireland, as practised by Brodigan in Slieven, is thus given. Hodges like those made for cucumbers are to be prepared in March, and the seeds, Mr. Brodigan does not seem to have known what species be cultivated, sown any time from the fifteenth of that month to the first of April. In the beginning of May the plants may be hardened by exposure to the air, and by the fifteenth or twentieth of that month they may be transplanted into the open field without injury. Forty thousand plants fit for transplanting may be raised on an area of one hundred square feet. According to Carver, a square yard will produce a hundred and thirty-two plants. The same method allows of the soil being kept free from the ridges. The field was prepared in every respect the same as for turnips; the drills or ridges were eighteen inches apart, and the manner, of which a good supply was given, buried in the centre of each ridge. The plants were put in with spaces, at eighteen inches apart, along the centre of the ridges, and they were followed by drills. The rows were afterwards covered with grass, with which they covered each plant, and confined by placing a stone or lump of earth at both ends; this covering is indispensable, unless the weather prove wet and cloudy. Such is the extreme delicacy of the plant that it will not live in the sun, until it is placed in the shade of the leaves of the plants; and supply the loss by evaporation. This will not be for some days, during which time the cover cannot be safely removed, and watering, to the extent of a pint a plant, may be daily used. Some of the respectable planters in the county of Wexford have used pots as a covering for the plants, of which some thousands will be necessary for each hogshead, cabbage, or potato, which are used for the same purpose. The experience has satisfied me that the mode 1 practised has decided advantages. It protects the plants sufficiently against the sun, and the water passes freely through it: whereas where pots or leaves are used, they must be removed to admit water, and in case of rain the plants receive little or no benefit from it. The operation of planting may be continued until the twentieth of June, but the earlier the better after the fruits have passed away. In America and France, I found, that four months were generally considered as necessary for the maturation of the plants; and that time in this climate cannot be allowed, unless they are put down early." (p. 160.)

641. The summer management of tobacco, by Mr. Brodigan, consisted in loosening the soil about the plants, removing the weeds, watering "for weeks together," taking off the decayed leaves at bottom, topping when the plant has from nine to fourteen good leaves, and removing the side buds as they appear.
6112. The curing process, by Mr. Brodigan, is as follows:—About the middle of August, the plants having obtained their full size, four or five of the bottom leaves of each plant are taken off, "suffered to lie on the ground for some time; and when they lose their brittleness, and can be safely handled, they are carried home to a barn, and there put in a heap for fermentation. The heap is turned, placing in the centre which was before in the bottom or exterior, and the temperature is not allowed to exceed 100° or 110°. After remaining two or three days in this heap, the leaves are spread out and cooled, and strung by the middle. When hung up thus, the other leaves then hung up, the leaves thus suspended have acquired an auburn colour, they are fit for a secondary fermentation. "A quantity of hay must be placed between the tobacco and the ground, and the heap may be made of an oblong or cone figure, the end of the stems being placed inwards. The heap being made, it is to be surrounded with trees, or with stakes, or with other covering. The period for this fermentation will depend upon the state of the weather, and the dryness and size of the leaves. In four or five days I generally found the heat sufficiently high to penetrate and reduce the stems, and when that is accomplished the heap is to be broken up, and may very strongly be reduced in a few days. In reducing very strongly, or a very important point of fermentation, or sweating the tobacco, I have given the result of my practice. For greater accuracy, and the benefit of the inexperienced, I have given it from a thermometer; but, at the same time, the hand and feeling of a practiced overseer can direct the process. As soon as the tobacco has been perfectly dried, the sun is still necessary to expel the moisture, and until the middle of October, or until the centre is dry, and any aromatic that may exist, different preparations are used in different counties. In Brazil the leaves are steeped in a decoction of tobacco and gun copal. In Virginia, I understood, they sprinkle the tobacco, in the packing process, with diluted rum and molasses; and in Ireland they sprinkle, in the packing process, with a solution of the green copper, or a decoction of tobacco stems, and it is dry to a dark red. Thus, the effect of this innocent application is to soften and improve the flavour, darken the colour of the tobacco, and render it, in appearance, a more merchantable commodity. The next and last operation is to tie the tobacco in portable packages, about two hales or perches."

6143. Improvements in the curing process. Some of Mr. Brodigan's tobacco, he informs us, only wanted ace to be as good as Virginia. Tobacco improves by a sea voyage, as it undergoes a certain degree of fermentation in the hogheads in the spring or summer months. Drying houses heated by fires or steam, as near the coast, as improved are extremely beneficial. Captain Basil Hall visited a tobacco plantation on James River, and found the house in which the hands were hung up with fires of wood upon the earthen floor. The flavour of the wood burnt in this way, Mr. Brodigan states, is now thoroughly perceptible in the tobacco of late years imported from America.

6144. As suggestions derived from considering what we have read and observed on the subject of cultivating and curing tobacco, we submit the following.

6145. Where a farmer, who thoroughly understands and successfully practises the Northumbrian mode of cultivating turnips, intends growing tobacco, I recommend him to prepare the soil exactly as for Swedish turnips, give a double dose of well-rotted manure, mix the haly with forty times its bulk of sand or bone dust, and sow with Common's turnip seed, usually called French's, about the middle of May. When the plants come up, they may be thinned out as turnips are, to sixteen or eighteen inches apart, and topped up; the first cropping of August is best, about one month after beginning of July. It is best that they should be matured, as in Alsace, drying, however, in a barn or house heated by an iron stove. A cottager, or space cultivator, may find it worth his while to sow in a hothed or in a flower pot, and transplant; he may dry his leaves the whole time under the eaves of his cottage, and the second March is his gurget; or if the turf is dry, and any aromatic that may exist, different preparations are used in different counties. In Brazil the leaves are steeped in a decoction of tobacco and gun copal. In Virginia, I understood, they sprinkle the tobacco, in the packing process, with diluted rum and molasses; and in Ireland they sprinkle, in the packing process, with a solution of the green copper, or a decoction of tobacco stems, and it is dry to a dark red. Thus, the effect of this innocent application is to soften and improve the flavour, darken the colour of the tobacco, and render it, in appearance, a more merchantable commodity. The next and last operation is to tie the tobacco in portable packages, about two hales or perches."

6146. Produce. According to Morse (American Geography), "An industrious person in Maryland can manage 6000 plants, which, at a yard to each plant, cover considerably more than an English acre of ground:—the produce of these 6000 plants is 1000 lbs. of tobacco. 'A hogshead,' says Warden, 'weighing 1350 lbs., is considered a good crop, and sufficient employment for one labourer. In general four plants will yield a pound, though very rich land will yield double the quantity. On the fresh, rich lands of Kentucky, from 1000 to 1500 lbs. are raised per acre.'" (Brodigan, p. 189.) The leaves of four plants in Virginia make one pound of tobacco. According to Brodigan, the average produce in the county of Wexford is 1200 lbs. per English acre. In Meath, he has had 1680 lbs. per English acre. The money cost of production he estimates at 18l. where the land is prepared by horse labour, and 30l. where it is prepared by manual labour, per English acre. The produce, at 16l. 8s. per hogshead of 1350 lbs., barely pays the expense.

6147. To save seed. Allow a few of the strongest plants to produce their flowers; they will have a fine appearance in July and August, and in a favourable season each plant will ripen as much seed in September as will sow a quarter of an acre by the drill system of culture, or stock half a dozen acres by transplanting.

6148. The value of tobacco as an agricultural crop is much diminished, from the circumstance of its producing no manure.

6149. "The arguments of the immortal Jefferson against the culture of tobacco, and in favour of wheat, have been so often repeated, that it is not necessary to be particular. Jefferson did not wish the produce of that state to have to compete with that of the fresh lands of the western country. It is perfectly true, that where tobacco is generally cultivated, its picture of wretchedness is realised. It is the scene of France, in the wine districts, where the people are half-starved, and the crops, and other vegetables and fruit it produces, are the most wretched of all that country. It is the same in America as with sugar in the West Indies, both are cultivated from their relative advantages over other crops. Sugar is more profitable than tobacco in the West Indies, although the tobacco grown there is of superior quality, and tobacco is preferred in America to wheat, where the soil and climate admit of its cultivation. In some situations it is grown as a matter of necessity; such is the richness of their alluvial and fresh lands, that wheat cannot be produced until that excess of fertility is reduced by a course of
TOBACCO.

They had found that it is better to risk one dollar a bushel than tobacco worth two dollars per hundred weight. (Ibid. p. 127.) As a source of labour, the cultivation and cure of tobacco is a desirably employment for the rural population of Ireland. Its great advantage is that it affords employment for those intervals when the labouring poor are at present destitute of employment. The cultivation of tobacco as a crop is so very extensive as that crop is planted, there is a long interval of idleness and distress. The stock of potatoes is then generally exhausted or unfit for use, and the summer months are the most pinching times with the poor. The planting of tobacco occurs in March or April. It commences when the ridge is thoroughly prepared by hoeing the interval until the corn harvest. Again, between the corn harvest and the taking of the potatoes there is another interval of idleness, and that is occupied in the curing of the tobacco."

As a cleaning crop and a preparation for wheat, it must be at least equal to the potato.

The analysis of the tobacco stalk is given by Mr. Bridgman on the authority of Mr. Davy of Dublin. The object was to ascertain whether the stalks contained any quantity of the tannin principle, of alkalai, or of any useful vegetable substance.

The presence of the tannin principle could not be detected; and the alkalai afforded was not very considerable. The included fifty-eight, which a yield of six acres, a quarter of alkali, mostly potash. The stalks contain nearly one tenth of their weight of tobacco; and where tobacco is employed either in fumigating or in making decoctions for the destruction of insects, it may be useful to know, that part of the stalks will always produce effects equal to one part of the leaves.

Diseases and enemies. "In Virginia, the diseases and injuries to which tobacco is liable, are, in the language of the planter, worm-holes, ripo-shot or sun-burnt, moon-burnt, house-burnt, stunted by growth, torn by storms of hail or wind, injured or killed by frost. In Ireland we are exempt from those damages, except what may arise from heavy gales, which, in exposed situations, lacerate and break off the leaves; or an early frost, which is seldom injurious before Michaelmas, at which time, if the planter be careful, he can have his off the ground." (Bridgman, p. 197.)

The same writer, however, enumerates the enemies of the tobacco in Ireland, as "the red or ring worm, which eats into wheat and corn, the grub, slug, caterpillar, and the tobacco-worm. Where the first two predominate in the soil, it is better not to plant tobacco; for there is no effectual mode of arresting their ravages. A correspondent in the county of Wexford has informed me, that two hedgerow insects, which are the attempts of six and seven, the plants were no sooner put down than they were cut off by the red worm; they planted again, and the same fate attended them; they planted a third time, and they were a third time destroyed. Thus all their labour and expense were lost; and in the month of July, they sowed the ground with turnips. The great damage to the plant to plant beneath the soil, secure from observation; he attacks the roots of the plants when grown to a considerable height, and thus prostrates a whole field. Where numerous, it is in vain that you seek for the enemy; but as soon as the plant appears sickly, it is admitted that it is a part of tea, and they are caught a pair of gloves. The other enemies are visible, and not so destructive. The slug attacks the young plants in the seed-bed and in the field, and destroys the young leaves: he will also cut the leaves of the tobacco in every stage of its growth, which is a proof that its caustic or poisonous property does not attach to it in the green stage. This insect generally appears in the warm months of July; it is large and of a voracious aspect. As soon as the leaves appear perforated, this enemy must be sought for, and he will be found in the day-time in the shaded parts of the plants. The caterpillar appears to exist only in close and warm situations." (Bridgman, p. 16.) Lime water or cow urine effectually destroys slugs, snails, and worms, and probably some of the sorts of caterpillars.

The manufacture of tobacco we have slightly described in the Encyclopaedia of Plants. We have since had an opportunity of witnessing the progress of all the different operations carried on in preparing shag and other kinds of smoking tobacco, pigtail and other chewing tobacco, various snuff, and different kinds of cigars, in one of the most extensive manufactories in London; and the conviction on our mind is, that very little in the way of manufacturing can be attempted by the gardener or cottager.

That little we shall shortly describe.

The tobacco, being properly fermented and cured, may be kept closely pressed and excluded from air, in casks, till wanted; or when the curing process is completed, smoking tobacco and snuff may be made from it as follows:—Open out the leaves singly, and from each tear out the midrib. The midribs are better adapted for rapping into snuff than for cutting into shag for smoking; and being scented by any essence, such as that of thyme, anise, lemon, or more especially by that of the root of Ficus olensina, theorris root of the druggists, may be tied up in what are called carrots, or rolls, about eighteen or twenty inches long, two or three inches in diameter in the middle, and half an inch at each end. They are tied with packthread drawn as tight as possible, and the threads quite close, so as to compress the tobacco into one solid substance, and completely to exclude the air. When snuff is wanted, unroll a part of the packthread at one end, and rasp the tobacco into snuff with a file or grater. The carrot is dried dry place the dry parts of the leaves may be made in the same manner, and a soft part produced which some prefer to the other. Gardeners may dry leaves of any odoriferous plant, such as thyme, mint, Aloysia citridora, &c., and tie them up in the tobacco carrot as substitute for liquid scent; and, if thought necessary, they may add a leaf of mint, or an infusion of the same, and various other plants, which may be added. The soft parts of the leaves, from which the midribs have been removed, may be slightly sprinkled with water, without any admixture whatever, and twisted into a rope, about the thickness of a common straw, and thus dried. They are then divided up into liberal pieces, and compacted three or two places with packthread, wrapped in paper, and placed in a dry situation, excluded from the air, till wanted for use. When to be used for smoking, cut off a few inches of the rope, open it out, and cut it into shags with a knife or chopper, so that it may be made into shag tobacco, or mix with the leaves on the fire over the coals. To make the leaves into tobacco for cigars, tear them into pieces an oven, and pound them in a mortar, adding to the powder any scented water, or volatile odoriferous oil, at pleasure. More snuff is made than is wanted for immediate use, put it in a glass bottle, and cork it close. In manufacturing cigars, there are various matters are used. The three principal kinds are Scotch, Spanish, and Portuguese. The first is only granulated, the second is reduced to a very fine powder, and the third consists of the sections of the second sort. The Scotch and Irish snuffs are, for the most part, made from the midribs; the Strasburgh, French, and Russian snuffs from the soft parts of the leaves.

The process of forming cigars is very simple; but, as it cannot be done well without much practice, it would be of little use to offer a description. Whoever wishes to make himself master of all that is known on the culture of tobacco in different parts of the world, and all the different modes of its manufacture,
PRACTICE OF AGRICULTURE. Part III.

SUBJECT 4. Other Plants used in Domestic Economy, which are or may be cultivated in the Fields.

6157. Many garden plants might be cultivated in the fields, especially near large towns, where manure is easily procured, and a demand for the produce exists. Among such plants may be mentioned the cress, parsley, onion, leek, lettuce, radish, &c. There are also some plants that enter into the agriculture of foreign countries where the climate is not dissimilar to our own, which might be very effectually cultivated in this country were it desirable. Among these is the chicory, the roots of which are used as a substitute for coffee. The lettuce might be grown for its milky juice, as a substitute for, or rather a variety of opium. Of dwarf fruits, as the strawberry, currant, gooseberry, raspberry, &c., we add nothing here, having already alluded to them in treating of orchards.

6158. The agriculturist who attempts to grow any of the above plants can hardly expect to succeed unless his knowledge extends beyond the mere routine of country husbandry, either by reading and the study of the nature of vegetables, or by some experience in large-scale. No farmer on a large scale will find it worth while to attempt such productions, whatever may be his knowledge or resources; and for the garden-farmer, or the curious or speculative amateur, we would recommend observation and enquiry round the metropolis, and the reading of books on horticulture. All that we shall do here, will be to give some explanation of the culture and management of cress and chicory.

6159. The garden cress (Lepidium sativum L.), too well known to require any description, is grown in the fields in Essex, the seed being in some demand in the London market.

6160. It is sown on any sort of soil, but strong loam is the most productive. After being well pulverised on the surface, the seed is sown broadcast and lightly harrowed in. The season of sowing for the largest produce is March, but it will ripen if sown the first week in May. The quantity of seed to an acre varies from two to four pecks, according to the richness of the land; the seed will not grow the second year. No after-culture is required but weeding. The crop is reaped and left in hand till to dry for a few days, and then threshed out like rapsed or mustard in the field.

6161. The use of the cress seed is chiefly for sowing to cut for young turkeys; and for forcing salads by the London cooks on hot moist tunnels and porous earthenware vessels. A very considerable quantity is also used in horticulture, it being one of the chief early salads, and cut when in the seed leaf. The haum is of very little use as litter, and, on the whole, the crop is exhausting.

6162. The culture of the chicory as an herbage plant has already been given (5314.), when grown for the root to be used as a substitute for coffee, it may be sown on the same soil as the carrot, and thinned out to the same distance as that plant.

6163. These roots are taken up in the first autumn after sowing in the same manner as those of the carrot. When they are to be manufactured on a large scale, they are partially dried, and in that state sold to the manufacturers of the article, who wash them, cut them in pieces, roast them on a kiln, and grind them between fluted rollers into a powder, which is packed up in papers, containing from two ounces to four pounds. In that state it is sold either as a substitute for coffee, or for mixing it with sugar, or being ground in a coffee mill. When a proper frame is not at hand for manufacture, the roots are laid in a collar among sand, and a few taken out as wanted, washed, cut into slices, roasted in the coffee roaster till they become of a brown colour, and then passed as wanted through the coffee mill.

6164. The value of the cress as an article of provision, Von Thunen observes in 1810, is proved by its having been cultivated for that purpose for thirty years. Dr Howison has written some curious papers on the subject in The Caledonian Horticultural Memoirs (vol iv.), and both that gentleman and Dr Duncan approve of its dictive qualities. The former indeed says, he thinks it preferable to coffee, which may be a matter of taste, as some prefer the flavour of the powdered roots of dandelion to that of either coffee or chicory. Dr Duncan is of opinion that chicory might be cultivated with great national advantages as a substitute for the exotic berry. (Discon. to Caled. Hort. Soc. 1831.) Boase says the decoction of chicory roots is wholesome, but that it has nothing more belonging to it of coffee than the colour. He sees no objection to its use as a substitute, but deprecates as fraudulent its mixture with the powder of real coffee.

6165. The value of the chicory as a salad plant appears to us not to be sufficiently appreciated in this country. Great quantities of the blanched leaves of chicory are sold in the markets of the Netherlands, the blanched and a little wased leaves for making salads being taken up on the approach of winter, and packed in cellars in alternate layers of sand, so as to form ridges with the crowns of the plants on the surface of the ridge. Here, if the frost be excluded, they soon send out leaves in such abundance to afford a supply of salad during winter. If light is excluded, the leaves are perfectly blanched, and in this state are known under the name of Barbe de Capacit. On shipboard it is customary to use a barrel of sand with numerous holes (fig. 811.), or a large box of the same purpose. (Gard. Mag. vol ii. and Ency. of Gard.)

6166. The Astragalus baticicus (fig. 812.), an annual distinguished by its triangular pods, a native of the south of Europe, is cultivated in Hungary (§ 630.), and in some parts of Germany, for the seeds as a substitute for coffee. The culture is the same as that of the common pea or taro.
6167. In a former section (6055.) we have hinted that no farmer who cultivates the hop need be without a vegetable equal to asparagus, or fibre similar to that of flax to employ his servants in spinning; and from the foregoing observations it would seem that whoever has a garden may grow his own coffee and tobacco.

Sect. V. Plants which are or may be grown in the Fields for Medicinal Purposes.

6168. A number of medicinal plants were formerly grown in the fields; but vegetable drugs are now much less the fashion; a few powerful sorts are retained, which are either collected wild or are natives of other countries, and the rest of the pharmacopoeia is chiefly made up of minerals. It may safely be affirmed that there are no plants belonging to this section which deserve the notice of the general farmer; but we have thought it desirable to notice a few sometimes grown by farming gardeners, and which may be considered as belonging almost equally to horticulture and agriculture, or as points of connection between the two arts. These are the saffron, liquorice, rhubarb, lavender, mints, chamomile, and thyme.

6169. The saffron, or autumn crocus (Crocus sativus L., fig. 813. a.), is a biennial-rooted perennial, which has been long cultivated in the south of Europe, and since Edward III.'s time in England, and chiefly at Saffron Walden in Essex. It was abundantly cultivated there, and in Cambridgeshire, Suffolk, and Herefordshire, in the beginning of the seventeenth century; but the quantity of land under this crop has been gradually lessening for the last century, and especially within the last fifty years, so that its culture is now almost entirely confined to a few parishes round Saffron Walden. (Young's Essex.) This is owing partly to the material being less in use than formerly, and partly to the large importations from the East, often, as Professor Martyn observes, adulterated with bastard saffron (Cártamus tindicóris) and marigolds (Calendula officinalis).

6170. The bulbs of the saffron are planted on a prepared soil, not poor nor a very stiff clay, but, if possible, a hark mould on chalk. They are planted in July, in rows six inches apart across the ridges, and at three inches' distance in the rows.

6171. The flowers, which are purple, and appear in September, are gathered, carried home, and the stigma picked out, together with a portion of the style; these are dried on a kiln between layers of paper, and under the pressure of a thick board, to form the mass into cakes.

6172. The crop of an acre averages two pounds of dried cake after the first planting, and twenty-four pounds for the next two years. After the third crop the roots are taken up, divided, and replanted.

6173. The uses of saffron in medicine, domestic economy, and the arts, are various. It is digestive, sedative, anodyne, cephalic, opthalmic, &c.; but its use is not without danger: in large doses it promotes drowsiness, lethargy, vomiting, and delirium; even its smell is injurious, and has been known to produce syncope. It is used in sauces, by the Spaniards and Poles; here and in France it enters into creams, biscuits, conserves, liquors, &c., and is used for colouring butter and cheese, and also by painters and dyers.

6174. The liquorice (Glycyrrhiza glabra L., fig. 813. b.; Liquorizia officinalis H. B. 10493.) is a deep-rooting perennial, of the Leguminóseæ, with herbaceous stems rising four or five feet high. It has long been much cultivated in Spain; and since Elizabeth's time has been grown in different parts of England.

6175. The soil for the liquorice should be a deep sandy loam, trenched by the plough or plow, or the aid of both, to two and a half or three feet in depth, and manured if necessary. The plants are procured from old plantations, and consist of the side roots, which have eyes or buds. In autumn, when a crop of liquorice is taken up for use, these may be taken off and laid in earth till spring, or they may be taken from a growing plantation as wanted for planting. The planting season may be either October or February and March. In general the latter months are preferred. The plants are dibbled in rows three feet apart, and from eighteen inches to two feet in the row, according to the richness of the soil. The after-culture consists in horse-hoeing and deep stirring, in weeding, and in cutting over and carrying away the haulm every autumn after it is completely withered. As the plants do not rise above a foot the first season, a crop of onions or beans is sometimes taken in the intervals. The plants must have three summers' growth, at the end of which the roots may be taken up by trenching over the ground. These are either immediately sold to the brewers' druggists, or to common druggists, or preserved in sand, like carrots or potatoes, till wanted for use. They are used in medicine and porter-brewing.
6176. The *rhubarb* (*Rheum* palmatum L., fig. 813, c) is a perennial, with thick oval roots which strike deep into the ground, large palmate leaves, and flower-stems six or eight feet high. Its leaves are the best of all the kinds of rhubarb for tarts. The Society of Arts exerted itself for many years to promote the culture of this plant, as did Dr. Hope of Edinburgh. It has accordingly been cultivated with success both in England and Scotland; though the quality of the root produced is considered by the faculty inferior to that of the Russian or Turkey rhubarb, as Professor Martyn thinks, an inferiority probably owing to the moisture of our climate, and the imperfect mode of drying.

6177. In the culture of this plant, if bulk of produce be the object, then a deep, rich, loamy sand should be chosen; but if flavour, then a dry, warm, sandy loam, somewhat exposed to the sun, is the most suitable. Transplanting from seed-beds may be adopted; but the roots are never so handsome and entire. As soon as the plants appear, leave only one in a place. The plants increase by a pair in the angles of squares of four feet to the side. The after-culture consists in horse-hoing and stirring, both lengthwise and across; in ploughing in the same directions; in never letting the flower-stems rise higher than two feet, or show flowers or seed unless some is wanted for propagation; and in removing the decayed basal shoots every autumn. The plants, having stood three or four summers, may be taken up, and their main roots dried in a very slow manner by any of the following modes:—The common British mode of curing or drying the rhubarb, after cleaning the roots, is to cut them into sections, an inch or more in thickness, string them, and dry them in any lofts, laundries, or kitchens, in a gradual manner. This has long been the practice of private gardeners who grow the root for their own use, and has also been adopted by cultivators for the druggists. The rhubarb is cured in Tarrary by being thoroughly cleaned, the smaller branches cut off, and then cut transversely into pieces of a moderate size; these are placed on long tables or boards, and turned three or four times a day, that the yellow viscid juice may incorporate with the substance of the root. If this juice be suffered to run out, the roots become light and unserviceable; and if they be not cut within five or six days after they are dug up, they become soft and decay very speedily. Four or five days after they are cut, holes are made through them, and they are hung up to the air and wind, but sheltered from the sun. Thus, in a few months, the roots are completely dried, and arrive at their full perfection. The loss of weight in drying is very considerable; seven loads of green roots yielding only one small horse-load of perfectly dry rhubarb.

6178. The Chinese in curing rhubarb, after having cleaned it, by scraping off the outer bark, as well as the thin yellow membrane underneath, cut them in slices, an inch or two in thickness, and dry them on stone slabs, under which large fires are kindled. They keep continually turning these slices on the stone slabs; but as this operation is not sufficient to dry them thoroughly, they make a hole through them, and suspend them on lines, in a place exposed to the greatest heat of the sun, till they are in a condition to be preserved without further drying. A complete enumeration of all the experiments made in Britain for the culture and curing of the rhubarb up to 1805, is given by Professor Martyn in his *Economic Flora of Great Britain*. *Rheum* and of the Turkey, Russian, and Chinese rhubarb, in Thomson’s *Dispensatory, 5th edit. 1825, p. 459.* It has been alleged of late, that the true medicinal rhubarb is not the *Rheum* palmatum as hitherto supposed, but the *R. austrium* (fig. 814). This species appears to be peculiar to the great table lands of central Asia, between the latitudes of 31° and 46°, where it is found to flourish at an elevation of 11,000 feet above the level of the sea. Large quantities of the roots are annually collected for exportation in the Chinese provinces, within the lofty range of the Himalay as. The best is that which comes from Russia, as greater care is taken in the selection of its arrival at Kuchta, within the Russian frontiers, the roots are carefully measured and then hanged, and the leaves removed. Mr. Sweet has been informed that the stems of the leaves have the same effect as the root; only, of course, a greater portion of them will require to be used. They may be made up in a small Tart, like the stems of the common rhubarb. (Gard. Mag. vol. v. p. 161.)

6179. The *lavender* (*Lavandula Spica* L., fig. 813, d) is a dwarf odoriferous shrub of three or four years’ duration, grown in the fields in a few places round London, and chiefly in Surrey, for the spikes of flowers used by the druggists, perfumers, and distillers. The soil should be a poor dry calcareous gravel. The seeds should be sown in a garden in spring, and the plants may be transplanted in September or March following, in rows two feet apart, and kept free from weeds. The second season they will yield a few flowers, and a full crop the fourth, after which the plants will continue productive for five or six years. The spikes are gathered in June, dried in the shade, and sold in bundles to the herbalists, druggists, &c.

6180. *Thyme, wormwood, marjoram, savory,* and some other aromatics, are cultivated in the same manner, and for similar purposes. Being usually smaller plants, they should be planted closer; but to have much flavour the soil must be dry and calcareous.

6181. *Chamomile* (*Anthemis nobilis*) is a creeping perennial, grown for its flowers. It only requires to be planted on a poor soil, in rows a foot apart, and hoed between. It will produce abundance of flowers annually from June to September, which are gathered, and dried in the shade. They are sold by weight to the druggists and apothecaries. The double-flowered variety is, from its beauty, that commonly cultivated; but the single possesses more of the virtues of the plant according to its weight.

6182. The *mint* (*Mentha*), and especially the *peppermint* (*Mentha piperita*), are creeping-rooted perennials, cultivated on rich marshy or soft black moist soils for distilling. The plants are grown in beds with trenches of a foot or more in width and
depth between, so as to admit of irrigation. The sets are obtained from old plantations, and planted in rows across the beds at six inches’ distance every way, in March or April. No produce worth notice is obtained in the first year, but a full crop in the third, and the shoots will continue to produce for five or six years. The spikes of flowers, and in some cases the entire herbage, are cut over in June, as soon as the flowers expand, and carried immediately to the druggist’s still. Some growers distil it themselves.

6183. *The common valerian* (*Valeriana officinalis* L.) is sometimes cultivated for its roots for the druggists. It is a native plant, and prefers a loamy soil. In Derbyshire the plants, which are either procured from the offets of former plantations, or from wild plants found in wet places in the neighbouring woods, are planted six inches asunder, in rows twelve inches apart. Soon after it comes up in the spring the tops are cut off, to prevent its running to seed, which would spoil it. At Michaelmas, the leaves are pulled and given to cattle, and the roots dug up carefully, and clean washed; the remaining top is then cut close off, and the thickest part slit down to facilitate their drying, which is effected on a kiln, after which they must be packed tight, and kept very dry, or they will spoil. The usual produce is about 18 cwt. per acre. This crop receives manure in the winter, and requires a great deal.

6184. *The orchis or salep plant* (*Orodes mascula* L.) is a tuberous perennial, which grows plentifully in moist meadows in Gloucestershire, and other parts of the country. It flowers in May and ripens seeds in July. It has been proposed to cultivate it for its tubers to be used as salep; but the plant is very difficult of propagation from seed, and can hardly be multiplied at all by the root; and, though it may answer to collect the tubers and prepare them, it is not likely their culture will ever pay. As the plant is very abundant in some situations, it may be useful to know its preparation, which is thus described in *Phil. Trans.* vol. lx.

6185. *The bulb is to be washed in water, and the fine brown skin which covers it is to be separated by means of a small brush, or by dipping the root in hot water, and rubbing it with a coarse linen cloth. When a sufficient number of bulbs are thus cleansed, they are to be spread on a tin plate, and placed in an oven heated to the usual degree, where they are to remain six or ten minutes, in which time they will have lost their milky whiteness, and acquired a transparency like horn, without any diminution of bulk. Being arrived at this state, they are to be removed, in order to dry and harden in the air, which will require several days to effect; or, by using a gentle heat, they may be finished in a few hours. By another process, the bulb is boiled in water, freed from the skin, and afterwards suspended in the air to dry; it thus gains the same appearance as the foreign salep, and does not grow moist or mouldy in wet weather, which those that have been barely dried by heat are liable to do. Reduced, in the order, they solidify and dissolve in boiling water into a kind of mucilage, which may be diluted for use with a large quantity of water or milk. Thus prepared, they possess very nutritious qualities; and if not of the very same species as those brought from Turkey and used for making salep, they so nearly resemble them as to be little inferior. In Turkey the different species of the *Orodes* are said to be taken indifferently; but in England, the *Orodes mascula* is the most common. (Gloucestershire Report, 577.)

**Chap. IX.**

Marine Plants used in Agriculture.

6186. *All marine plants may be used as manure with great advantage, either in a recent state or mixed with earth.* It is used in this way more or less in all agricultural countries bordering on the sea, and in Britain in all those friths and estuaries, where, from the water not being at the maximum of saltiness, the plants which grow in it are not sufficiently charged with soda to render it worth while to burn them for the sake of the salt.

6187. *The use of sea-weed,* as an article from which kelp might be manufactured, seems to have been practically recognised in Scotland about the beginning of the eighteenth century. The great demand for kelp in the manufacture of glass and soap at Newcastle, and of alum at Whithby, seems to have introduced the making of this commodity upon the shores of the Forth, so early as about the year 1725. It began to be manufactured in the Orkney Islands in the year 1733. The method in the west shire and elsewhere, the making of kelp was not known for many years after this date. The great progress of the bleaching of linen cloth in Ireland, first gave rise to the manufacture of kelp in that kingdom; and from Ireland it was transferred to the Hebrides about the middle of the eighteenth century. On the shores of England the kelp plants are not abundant.

6188. *All marine plants may be used for the manufacture of kelp,* but the principal species in use on the British shores belong to the Linnaean genus *Fucus.* *Fucus vesiculosus* (fig. 815. a) is considered by kelp-makers as the most productive; and the kelp obtained is, in general, supposed to be of the best quality. *Fucus nodosus* (b) is considered to afford a kelp of equal value to that of the above species, though perhaps it is not quite so productive. *Fucus serratus* (¢), or black-weed, as it is commonly called, is neither so productive as the preceding, nor is kelp procured from it so valuable. This weed is seldom employed alone for the manufacture of kelp; it is in general mixed with some of the other kinds. *Fucus digitatus* (*Laminaria digitata* H. B. 15, 343.) (d) is said to afford a kelp inferior in quality to that obtained from any of the others; it forms the principal part of the drift-weed.

6189. *The plants are cut in May, June, and July,* and exposed to the air on the ground till nearly dried, care being taken to prevent them, as much as possible, from being exposed to the rain. They are then
burned in a rude sort of kiln, formed by digging a pit in the sand, or by enclosing a portion of the surface with loose stones. On the bottom of this kiln a peat fire is kindled, and the weed is gradually added, till

the fire extends over the whole floor; the weed is then spread lightly on the top, and added in successive portions. As it burns it leaves ashes, which accumulating towards evening, become semifused, and are then well stirred. Another day's burning increases the mass; and this is continued till the kiln is nearly filled, per acutae stricte. It consists of a cavity in the ground, over which bars of iron are placed; and on this the ware is burned, the ashes falling into the cavity, where they are well worked by the proper instruments.

K is generally divided into two kinds; the cut-weed kelp, and the drift-weed kelp; the former made from the weed which has been recently cut from the rocks, the latter from that which has been drifted ashore. The latter is supposed to yield a kelp of inferior quality. Some specimens of kelp, however, made from sea-weed which had been drifted ashore, tend to prove that this is not always the case. Where the weed has been exposed to rain during the process of drying, affords a kelp of inferior quality. It is of the utmost importance to the manufacturer of kelp, to keep his weed as much as possible free from rain. For this purpose many employ sheds; when these are not at hand, the weed which has been laid out to dry on the cliffs should be covered with a heap during the rain; when this cover should again be immediately spread out. It has often been matter of dispute, how old the plants should be before they are cut. In general, three years is considered sufficient: this, however, from some trials which have been made to ascertain this point, seems to be too long. From experiments, it appears, that the produce of kelp, from one ton of three years' old weed, is only eight pounds more than that from the same quantity of two years' old; from this we would conclude, that the weed ought to be cut every two years. Though perhaps less weed may be procured from the same extent of ground occupied by weed of two, than of three years' growth, yet the difference may not be so great as to render it worth while to allow the weed to remain for three years.

6191. In order to increase the quantity of kelp, it has been suggested to the Highland Society, that the seed of the Sal[s]sa Soda might be imported and cultivated at a small distance from the shore, with the design of mixing the plant with the sea-ware, for the improvement of the kelp. It was formerly imagined, that the barley plant would not produce any quantity of alkali, worth its cultivation, if planted in France; but in the year 1782, some spirited individuals procured a quantity of barley seed, and made a plantation on the coast of the province of Landes, in the province of Languedoc; and in the course of a few years they found, that the barley which they produced from these plants was of a quality equal to that which they usually procured from Alicant. Why, then, may not a similar attempt in our own country be equally successful?

6192. Other plants. If the growers of kelp could contrive to make some considerable plantations of the most productive of the kail, or of fumitory, wormwood, and other inland plants, which yield large quantities of potash, and collect the crop to burn with the other materials, the carbonate of potash resulting from their incineration would decompose the sea salt, and a great accumulation of carbonate of soda would be produced. It was proved long ago by Du Hamel, that the marine plants produced soda merely in consequence of their situation, for when they have been cultivated for some years in an inland spot they yield only potash.

6193. There are immense tracts of shore on the mainland and islands of Scotland which may be easily cultivated for the production of kelp, from which at present not one penny is derived. All the cultivation requisite is, to place whin or other hard stones, not under the size of the crown of a hat, upon such vacant spaces. Contracts have been made to plant shore lands in the Highlands with such stones, at the rate of 50l. per Scots acre. Such stones are generally to be found at high-water mark, on all the shores of the lochs of the Highlands. They are put into a boat at high water, then carried to the ground to be planted, and thrown overboard; on the ebb of the tide they are distributed regularly over the shore, preserving a clear space of one round every stone, which distance, after very minute examination, appears to be the most eligible for producing the greatest crop of ware. It is evident these stones should be of a round shape; as the more surface that is exposed to the alternate action of the air and water, so much more kelp ware will be produced from a given space of ground. In four years the first crop may be cut, which, on the above data will yield about four per cent. on the original expense. But the crop may be manufactured into kelp in every third year thereafter, which, on the same data, is equal to about five per cent. In this improvement there is no hazard of bad crops; and if the manufacture is begun early enough in the season, there is little danger to be apprehended from bad weather, it being understood that the operation of kelp-making can be carried on, should there be no more than two dry days in eight. (Highland Society's Trans. vol. vi.)

6194. The cultivation of barilla (Sal[s]sa Soda, Chenopodiaceae, a native of Spain), on a small scale, was tried in the gardens of Tynningham, the seat of the Earl of Haddington, in 1789, but without success, although planted under a south wall, in a most sheltered part of the garden. (J. M. in Gard. Mag.) The culture of this and other species is practised to some extent in the neighbourhood of Alicant in Spain, and the details given
in the Cours Complet, &c. art. Soude. The ground is brought into good tilth, and manured; and the seed sown broadcast in October or November: in the following spring the plants will be found an inch high, and must be kept clear of weeds till the month of August, when, being at its full growth, it may be mown or pulled up (for it has scarcely any roots), dried, and afterwards burnt in holes in the ground like kelp.

6195. The sea-wrack grass (Zostera marina; Fluviales) is found in abundance on different parts of our own shores, as at Yarmouth, the bays of the Orkney Islands, and other bays not exposed to the immediate fury of the ocean.

6196. It grows in banks of sand and mud, which banks appear to be held together principally by the roots of this plant, which are strong and succulent, and throw out numerous lateral fibres. It grows at such depths as to be left nearly dry by the ebbing of spring tides. During the autumn and beginning of winter these leaves are thrown on shore in large quantities. They are of a very imperishable nature, and may be kept for any length of time in fresh or salt water, without any apparent decay. In the Orkney Islands this grass is thrown ashore during winter in large quantities, and collected by the inhabitants with other marine plants into heaps, for manure. In these heaps it is allowed to ferment, and sometimes, before being applied, is mixed with earth or other materials. It is also used as thatch, and forms a more durable defence against the violent winds and heavy rains of that climate than straw. A few years ago, in consequence of premiums offered by the Highland Society, this grass was applied as a substitute for horse, hair, and stuffing materials and furniture: for this purpose it is carefully washed twice in fresh water, then dried quickly; and afterwards, any sea-weed that had got mixed with it picked out. In the Orkneys it is steeped in fresh water lakes for a week, then taken out and spread wet on the ground, and picked, while in this state, from extraneous matters. Exposure to drought for one day will make it sufficiently dry for packing. When dry, care must be taken, if the weather is windy, to gather it into heaps or cocks, otherwise it may be blown away, being then extremely light. It is sent to market in large bags of sacks, or twisted into ropes of the thickness of a man's thumb, and laid up tightly in heaps, covered with ropes of bent grass. It is sold at the Asylum for the Industrious Blind at Edinburgh, who employ it in stuffing materials. (Highl. Soc. Trans. vol. vi. p. 292.)

CHAP. X.

Weeds or Plants injurious to those cultivated in Agriculture.

6197. Every plant which appears where it is not wanted may be considered injurious, though some are much more so than others. A stalk of barley in a field of oats is a weed, relatively to the latter crop, but a thistle is a weed in any crop; weeds, therefore, may be classed as relative and absolute.

6198. Relative weeds, or such cultivated plants as spring up where they are not wanted, give comparatively little trouble in expatriating them. The most numerous are the grasses when they spring up in fields of saffron or lucern, or among corn crops in newly broken up grass lands. The roots of chicory, in fields that have been broken up after bearing that crop for some years, those of madder, liquorice, &c., are of difficult extirpation. When the potato crop has not been cultivated in a manure field, it is not allowed to shed its seed, they occasion trouble. Other cases will readily occur to the practical man, and need not be mentioned.

₇₃⁶. Absolute weeds, or such native plants as are considered injurious to all crops, are very numerous, and may be variously arranged. Some affect in a more peculiar manner corn-fields and tillage lands, and these are chiefly annuals, as wild mustard, wild radish, poppy, blue-bottle, cockle, dandel, &c.; or biennials, as the thistle; or perennials, as couch-grass, knot-grass, black-couch, polygonum, &c.; on lands laid down to grass for a few years, dock, ox-eye daisy, thistle, knot-grass, &c. Other least grass lands, and these are chiefly perennials such as crowfoot, one of the most difficult of weeds to extirpate; thistles, docks, rushes, edges, moss, and an endless variety of others. Some are more particularly abundant in hedges; of which the reedy and coarse grasses, as couch-grass, bronee-grass; the climbing and twining plants, as goose-grass (Galium Aparine); and the twiners, as bind-weed (Convulvulus), are the most injurious.

6200. With regard to the destruction of weeds, they may be classed first according to their duration.

₇₂. All annuals and biennials, as sand-wort (fig. 816, a), and sorrel b, are effectually destroyed by cutting over the plant at any point below that whence the seed leaves originated, as this prevents them from ever springing again from the roots. Perennials of the fibrous-rooted kind may be destroyed in the same manner, as the crowfoot, ragweed, the fibrous-rooted grasses, and many others. Some fustiform-rooted perennials may also be destroyed by similar means; but almost all the thick-rooted perennials require to be wholly eradicated.

₇₃. The perennial weeds, which require their roots to be wholly eradicated, may be classed according to the kind of roots. The first we shall mention are the stoloniferous roots or surface shoots of plants, by which they propagate themselves. Of this kind are the creeping cresses (Gnaphalium or wild tansy, potentillias, mints, strawberries, black couch-grass, and most of the Agrostideae and other grasses. The next are the underground creeping roots, as the couch-grass, Convulvulus arvensis, and other species of bind-weed, coltsfoot (fig. 816, e), sowthistle, several tetradynamous plants, as toadflax, Scrophularia, L. nuth, hedge nettle, black bind-weed, &c. Some of these, as the bindweed and corn-mint, are extremely difficult to eradicate: a single inch of stolone, if left in the ground, sending up a shoot and becoming a plant. They are to be uprooted and discarded as the most difficult of all to eradicate. Of this class are the Polygonum amphibium (fig. 817, a), the reed (Arundo Pheragnites), the horse-tail (Equisetum fig. 817, b), and some others. These plants abound in deep clays, which have been deposited by water, as in the carse and clay-vaies of Scotland. In the Carse of Falkirk for example, the roots of the Polygonum amphibium are found
over its surface. Were this tract left to nature for a few years, it would soon be as completely covered with the Polygonum as it must have been at a former age, when it was one entire marsh partially covered by the Frith of Forth. The horse-tail is equally abundant in many soils, even of a drier description; and the corn-thistle (Serratula arvensis, Fig. 817, c) even in dry rocky grounds. Lightfoot (Flora Scotica) mentions plants of this species dug out of a quarry, the roots of which were nineteen feet in length: it would be useless to attempt eradicating the roots of such plants. The only means of keeping them under, is to cut off their tops or shoots as soon as they appear; for which purpose, lands subject to them are best kept in tillage. In grass lands, though they may be kept from rising high, yet they will, after being repeatedly mown, form a stock or stem of leaves on the surface, which will suffice to strengthen their roots, and greatly to injure the useful herbage plants and grasses.

6203. **Tuberous and bulbous-rooted weeds** are not very numerous; wild garlic, arum, and bryony are examples; and these are only to be destroyed by complete eradication.

6204. *Remisse, fastiforms, and similarly rooted perennials*, of which rest-harrow, fern, and scabious are examples, may in general be destroyed by cutting over below the collar or point whence the seed-leaves have issued. Below that point the great majority of plants, ligaceous as well as herbaceous, have no power of sending up shoots; though there are many exceptions, such as the dock, burreock, &c., among herbs, and the thorn, elm, poplar, cherry, crab, &c., among trees.

6205. **Holdich has taken a different view of the subject of weeds**, and classed them, not according to the modes by which they may be destroyed, but according to the injuries which they do to the soil or the crop. He has divided them into two classes, weeds of agriculture, or arable lands, and pasture weeds.

6206. **Arable weeds** are arranged as, 1. those which infest samples of corn; 2. root or fallow weeds, and such others as are hard to destroy; 3. those which are principally objectionable as they incubate the soil; 4. underling weeds, such as never rise with the crop, nor come into the sickle. Under these heads, each weed in its respective division is treated of as to its deteriorating qualities and mode of destruction.

6207. The weeds which infest the sample are, 1. Barnel (Lilium temulentum); 2. Menyanthes (Menyanthes trifoliata); 3. Tare (Vicia tetrasperma); 4. Millet (Trifolium Mellitius officinalis); 5. Wild oats (Avena sativa); 6. Harriif (Gallium aparine); 7. Crop weeds (Nandix Feticus); 8. Black bindweed (Polygonum Convolvulus); 9. Snake-weed (Polygonum Rapalophilum); 10. Charter seeds, (Ninjas, Rhiphum, and Brisia Scapa); 2. Corn poppy (Papaver Rhoeas); 3. Blue-bottle (Centauræ Cyanus); 4. Mayweed (Papaver Rhoeas, Coffs); and 5. Corn marigold (Chrysanthemum segetum).

6208. The weeds which are principally objectionable as they incubate the soil are, 1. Charterlock, a name which is applied to four species of Cruciferae viz. Snapis arvensis and nigra, Rhiphum, Raphanalbum, and Brisia Scapa; 2. Corn poppy (Papaver Rhoeas); 3. Blue-bottle (Centauræ Cyanus); 4. Mayweed (Papaver Rhoeas, Coffs); and 5. Corn marigold (Chrysanthemum segetum).

6209. The weeds called underlings, or such as never rise in the crop, are, 1. Groundsel (Senecta vulgaris); 2. Annual meadow grass (Poa annua); 3. Chickweed (Stellaria media); 4. Shepherds' purses (Thlaspi binae pabae and erecta); 5. Spurry (Spergula arvensis); 6. Chamomile (Matricaria Chamomilla); 7. Father (Chenopodium album); 8. Compton corn seed (Fides albidus); 9. Flix-weed (Sphagnum Sophia); 10. Common fumitory (Fumaria officinalis); 11. Sand mustard (Sesamum muralis).

6210. **Pasture weeds** are, 1. Dwarv-thistle (Carduus acalabia); 2. Common chamomile (Anthemis nobilis); 3. Star-thistle (Centaurea Calcitrapa); 4. Ox-eye daisy (Chrysanthemum leucanthemum); 5. Great fleabane (Conyza squarrosa); 6. Cheese-reneet (Gallium verum); 7. Long-rooted hawkweed (Aphrigia autumnaliss); 8. Wild thyme (Thymus Serpyllum); 9. Shep's sorrel (Rumex Acetosella); 10. Knot-grass (Polygonum aviculare); 11. Yellow rattle (Rhinanthus Crista-galli); 12. Common carline thistle (Carrina vulgaris).

6211. **Pasture weeds** which generally prevail in lovely soils, and which also as are prevalent in clayey and dambo soils, are principally as follow: 1. Yellow coast-heath (Usnea graminata); 2. Marsh thistle (Carduus palustris); 3. Melian thistle (Carduus heterophyllus); 4. Meadow thistle (Carduus pratensis); 5. Common butter-burr (Tussilago Patens); 6. Common ragwort (Senecio Jacobaea); 7. Common daisy (Bellis perennis); 8. Common black knapweed (Centaurea nigra); 9. Broad leaved dock (Rumex obtusifolius); 10. Orchis (Orchis mascula, mascula, latifolia, morio, and pyramidalis); 11. Common cow-pea (Hedervarius Sphondyllum); 12. Sedge (Carex), various species.
their proper names. Besides, weeds which abound most, and are most injurious in one district, are often rare in another. Thus, the poppy abounds in gravelly districts, the charlocks on clays, the chickweed, groundsel, nettle, &c., only on rich soils. A local Flora, or any of the national Floras, as Lightfoot's Flora Scotica, and Smith's British Flora, and, we may be allowed to add, our own Encyclopedia of Plants and Hortus Britannicus, by pointing out the habits of indigenous plants, may be of considerable use to the agriculturist who has acquired a slight degree of the science of botany.

BOOK VII.

The Economy of Live Stock and the Dairy.

6213. The grand characteristic of modern British farming, and that which constitutes its greatest excellence, is the union of the cultivation of live stock with that of vegetables. Formerly in this country, and in most other countries, the growing of corn and the rearing of cattle and sheep constituted two distinct branches of farming; and it was a question among writers, as, according to Von Thaer, it still is in Germany, which was the most desirable branch to follow. The culture of roots and herbage crops at last led gradually to the soiling or stall-feeding husbandry, in imitation of the Flemings; and afterwards, about the middle of the last century, to the alternate husbandry, which is entirely of British invention, and has been more effectually than any thing else the means of improving the agriculture of the districts where it is practised.

6214. It is observed by Brown, that "though horses, neat cattle, sheep, and swine are of equal importance to the British farmer with corn crops, yet we have few treaties concerning the animals, compared with the immense number that have been written on the management of arable land, or the crops produced upon it. But though so little has been written, the improvement of those animals has not been neglected; on the contrary, it has been studied like a science, and carried into execution with the most sedulous attention and dexterity. We wish it could be stated, that one half of the care had been applied to the selecting and breeding of wheat and other grains, which has been displayed in selecting and breeding the best proportioned and most kindly feeding sheep. A comparison cannot, however, be made with the slightest degree of success; the exertions of the sheep-farmers having, in every point of view, far exceeded what has been done by the renters of arable land. Even with cattle considerable improvement has taken place. With horses, those of the racing and hunting kinds excepted, there has not been correspondent improvement; and as to swine, an animal of great benefit to the farmer, in consuming offal which would otherwise be of no value, it is to be regretted that very much remains to be done."

6215. The first important effort in the improvement of live stock was made by Robert Bakewell, who was born on his father's estate of Didley, in 1726. Mr. Bakewell wrote nothing himself; so the first scientific work on the subject was written by George Culley, in 1782, who had formed himself on Bakewell's model. The systematic improvements of Mr. Bakewell were developed in various agricultural reports, and consisted in attempts to lessen such parts of the animal frame of cattle and sheep as were least useful to man, as bone, cellular substance, and appendages; at the same time increasing such other parts, as flesh or muscle, and fat, as become more important in the furnishing man with food. These ends he endeavoured to accomplish by a judicious selection of individuals, possessing the wished for form and qualities in the greatest degree; which being perpetuated in their progeny in various proportions, and the selection being continued from the most approved specimens among these, enabled him at length to establish breeds with the desired properties. Later improvements have been grafted on these, and we find excellent observations on the subject from the pens of Cline, Dr. Coventry, Sir J. Sebright, Hunt of Leicester, and the Rev. H. Berry; and we have witnessed the strenuous and successful efforts of a Russell, a Coke, an Ellman, and others. The improvement in the sciences of comparative anatomy and physiology has also led to an amended practice both in breeding and in pathology. The example of various opulent proprietors and farmers in all parts of the empire tended to spread this improvement, by which the pursuit became fashionable. Add to these the accounts of the management of live stock in almost every county of the British Isles, as contained in Marshall's Works and the County Reports. From these sources we shall draw the information we are about to submit, and shall adopt the arrangement of the horse, the ass, the mule and hinny, the bull family and the dairy, the sheep, the swine, minute stock, and injurious animals or vermin.

CHAP. I.

6216. The horse family, by far the most important among the brute creation as a servant to man, includes several species both in a wild and cultivated state, as the E. hemionus, or wild mule, a native of Arabia and China, and which it is supposed would form an excellent race of small horses, could they be reduced to a state of domestication; the E. Asinus, or ass, well known; the E. Zebra, or striped ass; the E. Quagga, by some considered a variety of the zebra; and the E. bisulcus, or cloven-footed horse, a native of Chile, and by many supposed to belong to a distinct genus.
The common horse, justly considered as the noblest of quadrupeds, is found in a wild state in the deserts of Great Tartary, in the southern parts of Siberia, and in other parts of Asia, and in the interior of Africa. He has long been domesticated and cultivated in most parts of the earth, for the various purposes of war, hunting, parade, the saddle, and draught; and in some places, partly for his flesh and the milk of the female. The parts of a horse, when no longer endued with life, are applied to various useful purposes. The blood is used as manure. The bones are broken and boiled, to produce oil, and are afterwards ground into an excellent manure; some of the bones are also employed in the mechanical arts. The flesh supplies food for the domestic carnivorous animals, the cat and dog; for carnivorous birds, kept for amusement or curiosity; for fish, &c.

We shall consider the horse in regard to its varieties; organology, anatomy, physiology, diseases, breeding, rearing, training, feeding, and working.

Sect. I. Varieties of the Horse.

The varieties of the domestic horse are numerous. The indigenous horse of every country, operated on by climate, assumes that form best adapted to its locality. Man would soon, however, be led to mix with the native breeds that variety which presented in its aboriginal state the finest form and most valuable qualifications. This being found centred in the horses of Arabia, Persia, and Barbary, the inhabitants of Europe generally sought an amelioration of their own breeds by an admixture of oriental blood.

The Arabian horses (fig. 818. is a portrait of one brought by Buonaparte from Egypt, and now living in the royal garden of Paris) are reckoned the best, and the solicitude with which the Arabs preserve these horses pure and unmixed is remarkable. The care with which they are nurtured, and the skill displayed in their equestrian management, are no less admirable. None but stallions of the finest form and purest blood are allowed access to their mares; this is never permitted but in the presence of a professional witness or public officer, who attests the fact, records the name, and signs the pedigree of each. The Persian horses are considered next in value; and after them the horses of Andalusia in Spain. The Barbary horses are descended from the Arabians, and much esteemed. Jackson (Empire of Morocco, p. 42) mentions one very fleet variety, used for hunting the ostrich, and fed entirely on camel's milk. The horses of India, though active and not ill formed, are small and vicious, the climate being unfavourable to their greater development. Those of Tartary are of a moderate size; but strong, muscular, full of spirit, and active. The Tartars are considered skillful riders. Like the Kalmucks, they eat the flesh of horses as we do that of oxen, and use their milk either in curd or fermented. The horses of Barbary, however, are esteemed the choicest; and in this respect they are naturally the most improved. The English horses, though their carriage may be traced to a mixture of their native breeds with the Asiatic introduced by the irruption of the Goths, and originally received from the Scythians, and the true eastern blood received from Spain, Barbary, and Arabia. With these admixtures, however, the horses of France have not yet borne a high character throughout Europe; and although under the dominion of Napoleon more than two hundred horses of various strains and breeds of horses were imported, and were imported in great numbers, there were no improvements. Northern states plunders of their choicest specimens, by which the breeds have been much improved; still France imports yearly vast numbers from this country, particularly hunters and high bred carriage horses. Of their own breeds, Linnéus furnishes some good accounts, and he also remarks that those, Normandy claims precedence for a well-formed and useful breed. There are also very good hotots, or ponies, in Auvergne, Poitou, and Burgundy. Lower Normandy and the district of Cotentin furnish some very tolerable coach horses, and which are more suitable for cloisters than any of the Dutch horses. They have, however, a noble race of large draught horses equal to any seen in England, and among which the chestnut colour seems to prevail. The French horses generally are apt to have their shoulders although oblique, yet too loose and open, as those of the Barbs are usually too extended and narrow.

The Flemish horses are inferior in value to the Dutch, having usually large heavy heads and necks; their feet also are immoderately large and flat, and their legs subject to watery humour and swellings. Holland furnishes a race of horses which are principally serviceable in light draught work; the best come from Friesland.

Germany is not destitute of good horses. The native breeds, heavy and ill-formed, received their first improvement from admixture with the Asiatic horses. In after-times the Germans obtained still
finer breeds from the Arabs, Turks, and the Barbery states, which they still preserve with some care as stallions; some good specimens are also obtained from Spain. In a general point of view, however, the German horses are no more fitted for the same purpose, and are inferior to the Hungarian and Transylvanian horses. The horses of Bohemia are not distinguished by any eminent qualities. The Russes and Transylvanians are accustomed to sit the nostrils of their horses, under a notion of giving their breath a free passage, and they have, as well as to render them incapable of neighing, which, in the field, would be often inconvenient. The Croatian horses are nearly allied in qualities and character to the Hungarian and Bohemian: these, as well as the Poles, are remarkable for being, as the French term it, bsuit, or keeping the mark in their teeth as long as they live.

6259. The Polish horses are hardy, strong, and useful, but they are generally of a middling size. In the marshy parts of Prussia, and towards the mouth of the Vistula, there is a breed of tall strong horses, resembling those of Friesland, but without their inferior value.

6260. The horses of Russia are not much regarded by other nations. They are small but hardy, and capable of enduring great fatigue. Great attention is, however, paid to such as are very fast in their trot; and such a breed is much encouraged. Their trotting matches on the frozen lakes and ice, which are harnessed and finely shaped, but too slight and weak for heavy cavalry. The Kalmucks horses are somewhat higher than the Russian common horses, and are so lasting and constitutionally strong as to be able to run three or four hundred English miles in three days. They subsist entirely on hard bread, and are between the right sort of Don, Volga, and Yaik, where they are collected in great herds of four hundred, five hundred, or even a thousand. They are excellent swimmers, and pass the river Volga, where it is from one mile to two miles broad, with great ease.

6261. The horses of Sweden are low and small, comprehended under the same description, but they are strong, hardy, and active. Denmark, and also Holstein and Oldenburg, boast a large variety of horses, which has long been esteemed as peculiarly adapted for heavy cavalry and carriage uses, though they are apt to fail with regard to grace of parts; their necks, by the most judicious management of their breeders, have back long, with croups too narrow to correspond with their fore parts. In the Islands of Feroe there is a race of horses of small growth, but strong, speedy, and very sure-footed. They are never shod, and feed abroad without shelter both summer and winter. In the West Indies, particularly swift and active peruvians, of which the breeders, who watch their sheep, which are wild, by hunting them with a dog, pursuing them at the same time with their horses. The horses of Lapland are small of stature, but active and willing; they are used only in the winter season, in drawing sledges over the snow, and transporting wood, forage, and other necessaries.

6262. The British varieties of saddle horses may be reduced to the racer, the hunter, the improved hack, the old English road horse, the galloway, and the pony; the two latter of which we shall consider in another place.

6263. The race horse (fig. 819.) is descended nearly in a direct line from the Arabian, the Persian, and the Barb. In an agricultural point of view, this celebrated breed might at first sight appear of little importance; but it is probable that to the amusement afforded by it to the rich and powerful, we are indebted for the principal improvements in every other variety of the most valuable animal. Races or courses were very early a part of British sports; and it is natural to suppose that, on this account, endeavors would be made to improve and enlange the breeds of the native horses. Roger de Bellesme, Earl of Shrewsbury, is the first on record who imported a Spanish stallion, the progeny of which was afterwards exalted by Michael Drayton, in his Polyolbion; and, it is probable, the first amelioration of the native breeds was derived altogether from horses of Spain and the southern parts of France.

6264. In the reign of Henry IV., public ordinances were made favourable to the improvement of the breeding of horses, which would tend still further to extend the search after better specimens. There is between sixty and seventy breeds of horses, or improved breeds, and they are all improved for different purposes, and some are to be bred for the race, others for the hunter, and others for the hack, from Spain, the southern parts of France, the Barb, and the Arabian horse. One of the best is the Jockey, which has been bred for the purpose of being ridden by celebrated jockeys in the English race.

6265. Climate has a great influence over the form of animals, and that form is found indigenous to each which best fits it for the purposes required of it. In the arid plains, where the climate is very hot, the animal, in a form is given which enables it to endure the heat of the sun. And as in every situation the flesh of the horse is greedily sought after by the predatory tribes, so here, where those are peculiarly strong and active, the horse is formed peculiarly agile and swift. It is the same in the sandy deserts, where the form is to be highly extended, as in the marshy districts, where the horse is to be essentially heavy and strong. Symmetrically formed as we now see him, he at once exercises his claim to great speed. His bony skeleton exhibits a base founded on the justest geometrical principles, preserving an unalterable proportion of lengthened levers acting by means of a condensed muscular and tendinous organization of great power, on angles capable of great flexion and extension; while his pointed form fits him to cleave that atmosphere, from which his deep chest enables him to draw by extensive inspirations wind and vigour to continue his exertions. Purity of blood, by which is meant the result of confining to particular races or
Breeds the means of continuing their species, is observed with equal rare and jealousy by the breeders of the English race, as by the Arabians; and turf jockeys assert they can discover a taint or departure from this purity to the utmost romove.

6254. The hunter (fig. 820) is derived from horses of entire blood, or such as are but little removed from it, uniting with mares of substance, correct form, and good action. In some instances hunter horses are produced from large mares of the pure breed, propagating with powerful stallions of the old English road horse. This is a favourite and durable breed is a mixture of the blood of the old English road horse. The improved hackney (fig. 821.) was derived, like the former, from a judicious mixture of the blood breed with the native horse, but exhibiting a greater proportion of the latter. Hackneys are now, however, mostly bred from stallions possessing nearly the same proportion of blood with the hunter; but with a form and qualities somewhat different. In the hackney, as safety is as requisite as speed, we look particularly in the fore parts to see that they are high and well placed; that the head is not heavy, nor the neck disproportionately long or short; that the legs stand straight (that is, that a perpendicular line drawn from the point of the shoulter to the ground shoule meet the toe); and that the elbows turn out: and although a perfect conformation in the hinder parts is necessary to the hackney, it is in some measure subordinate to the same perfection in the fore parts; whereas in the racer and hunter, but particularly in the former, the form of the hinder is even of more consequence than that of the fore parts.

6255. The old English road horse. The old English road horse is now nearly extinct, although some northern agriculturists appear to be making efforts to revive the breed. It is so far known in this country that it was originally from a judicious culture from horses of Norman, German, or Flemish extraction, which horses were very early imported to enlarge our small breeds, and to render them capable of the heavy loads they were com- ptoned to carry as pack-horses; and of which kind the old English road horse unquestionably is. (fig. 822.) Neither is it at all impossible, that, in the more fertile parts of the island, an original breed of considerable power and bulk. Athelstan expressly prohibited the exportation of English horses, and the "scythe chariot" or fiery steeds of the ancient Britons struck terror even into Caesar's legions. These accounts of the ancient horse of the English race, received additional strength from the notices we obtain of the fossil bones of horses having been found, according to Parkinson, in various parts of the island. The old English road horse possessed great power, with short joints, a moderate shoulder, elevated crest, with legs and feet almost invariably good. The heights varied from fifteen to eighteen hands, and the colours were frequently mixed.

6255. The objection, howev., to English horses, both of the original and of the more early improved breeds, and which is even still seen among them, is, that they are not of so expressive in their action and carriage; that they are somewhat obstruct and sullen; and that a certain stiffness in their shoulders, and want of suppleness and elasticity in their limbs, render them unfit for the manage. As this is an im- portant charge against the excellence of our breeds, it may be worth considering how far the improved breeds of continental horses, the fore parts of which are often much higher, and the latter parts not raised to such an extent as in the English breeds, and by which, flexibility and safety in progression are gained at some expense of celerity; for the strong lumbar muscles of horses so formed, operating on the lengthened spinous processes of the dorsal vertebrae with increased advantage, raise the horse, and increase his speed; whereas in the English breeds, a part of the strength is used in levering, and the celerity is the result of the sudden movement; the former, consequently, can be opened, and secondly, on the efforts of the body in the progression, to render the limbs the common centre of gravity, the earth; so it is evident that the form which is the most favourable to speed, is both so to safety or flexibility in progression.

6256. The Irish road horse, or hunter, equal with, or probably in some measure subsequent to, the culture of the old English road horse, was a still more excellent breed. With similar properties, but an improved form, with a great acquired aptitude for leaping, it gained the name of the Irish hunter; and when the dogs of the chase were less speedy than they now are, this horse was equal to every thing required of him as a hunter; even now the possessors of the few which remain find, parti- cularly in an enclosed and deep country, that what others gain by speed these accomplish by strength to
go through any ground, and activity sufficient to accomplish the most extraordinary leaps. As road-
sters, these horses have ever proved valuable, uniting durability, ease, and safety with extreme docility.

In form they may be considered as affording a happy mixture of an improved hack with our old
English roadsters.

623. The British varieties of saddle horse of more inferior description are very numerous, as cobs,
galloways, and ponies. Cobs are a thick, compact, hackney breed, from fourteen hands to fourteen hands
two inches high, in great request for elderly and heavy persons to ride, or to drive in low phaetons, &c.
(Galloways and ponies are late in touch request also for low chaises; a demand which will lead to a
cultivation of their form; the number bred requires little increa-e, as several waste districts or moors
throughout England are already appropriated principally to the purpose of rearing ponies.

623. The British varieties of war or cavalry horse, and of carriage and cart horse, are considered to
have been derived from the German and Flandish breeds, melerated by judicious culture. Most of the
superior varieties contain a mixture of Arabian or Spanish blood. Cavalry horses are found amongst the
larger sort of hackneys; and the observations made in the late wars sufficiently show the justice of the
selection. Except in a few unhappy instances, where a mistaken admiration of the Hulans had led to
selecting them too light, the English cavalry horse possessed a decided superiority over the best French
horses in strength and activity, as well as over the Germans, whose horses on the other hand, by their
bulk and heavy make, were incapable of seconding the efforts of the British dragoons. The coach, chas-
riot, and stage horses are derived many of them from the Cleveland bays, further improved by a mixture of
blood. Others are bred from a judicious union of blood and bone, made by the breeders in Yorkshire,
Lincolnshire, and other midland counties.

623. The varieties of draught horse were originally as numerous as the districts in which they were
bred, each having its favourite breed; but since the intercourse among farmers and breeders has been
greater, those in common use are so mixed as to render it difficult to determine of what variety they
partake the most. At present the principally esteemed draught horses are Low Countries, the Clevel-
land bay, the black, and the Lanark or Clydesdale. The native breeds of draught horses of England,
Scotland, Wales, and Ireland, are much too small for the purposes of agricultural draught as now con-
ducted; but by cultivation, the improved breeds pointed out have furnished such animals as are equal to
everything required of them.

623. The black horse (fig. 823), bred in the midland counties of England, is a noble and useful animal;
and furnishes those grand teams we see in the coal, Boar, and other heavy carts and waggons about London;
where the immense weight of the animal's body assists his accompanying strength to move the heaviest loads.
But the present system of farming requires horses of less bulk and more activity for the usual agricultural pur-
poses, better adapted for travelling, and more capable of enduring fatigue; consequently this breed is seldom
seen in the improved farms. The black cart horse is understood to have been formed, or at least to have been
brought to its present state, by means of stallions and mares imported from the Low Countries; though there
appears to be some difference in the accounts that have been preserved, in regard to the places whence they were
originally brought, and to the persons who introduced them. (Culley on Live Stock, p. 32, and Marshall's
Economy of the Midland Counties, vol. i. p. 306.) Marshall, under too confined a view, and probably prejudiced
against the breed on account of its fincnd want of spirit, as well as for the alleged tendency to become flat and
pommeiced in the feet, is most unreasonably severe on it, when he says, "the breed of grey rats, with
which this island has of late years been overrun, are not a greater blessing than the breed of black fo
horses; at least while cattle remain scarce as they are at present, and while the flesh of horses remains
sub-varieties of this breed is said to have taken its rise in six Zealand mares, sent over from the Hague by
the late Lord Chatham, during his embassy at that court.

624. The Cleveland bays (fig. 824), which owe some of their most valuable properties to crosses with
the race-horse, have been long celebrated as one of the best breeds in the island; but they are said to have
degenerated during late years. They are reared to a great extent in Yorkshire, the farmers of which are
remarkable for their knowledge in every thing that relates to the use and acquirement of animal activity and
hardiness, these horses, perhaps, have no superior. Some capital hunters have been produced by putting
full-bred stallions to mares of this sort; but the chief object latterly has been to breed coach-horses, and
such as have sufficient strength for a two-horse plough. Three of these horses draw a ton and a half of
coals, travelling sixty miles in twenty-four hours, without any other rest but two or three baits upon the
road; and frequently perform this labour four times a week.

624. The Suffolk punch (fig. 825) is a very useful animal for rural labour, and is particularly esteemed
by the farmers of Norfolk, Suffolk, and Essex, but the merit of this breed seems to consist more in
constitutional hardiness than in any apparent superiority of shape. "Their colour is mostly yellow

or sorrel, with a white rach or blaze on their faces; the head large, ears wide, muzzle coarse,
of-ter-cend low, back long sometimes, but always very straight, sides flat, shoulders too far forward, hind-quarters middling, but rather high about the hips, legs round and short in the pasterns, deep-bellied, and full in the flank. Here, perhaps, lies much of the merit of these horses; for we know, from observation and experience, that all deep-bellied horses carry food long, and consequently are enabled to stand longer and harder days' works. However, it is true, that these horses, in surprising days' works. It is well known, that the Suffolk and Norfolk farmers plough more land in a day than the merest of these people in the Island, and these are the kind of horses everywhere used in those districts. (Culley on Live Stock, p. 57.) Since Culley's time much pains have been taken to improve the breed, and to reduce cultivation, fitted not only for heavy but for light work. It is an uncommon thing for a Suffolk stallion to father a foal of over 30c. The best of these stallions in England is at Woodbridge Lady-day fair, where Suffolk cart horses have been brought from 100l. to 150l., and one mare and her offspring a few years ago at this fair brought 100l. The figure (825) hardly does justice to the animal. (31)

and usually black, with wide heels; the back straight, but not prominent, and the space between them and the ribs short, the tail heavy, and well haired, the thighs meeting each other so near as to leave only a small groove for the tail to rest on. One most valuable property of this breed is, that they are remarkably true pullers, a restive horse being rarely found among them.

6:44. The Welsh horse (fig. 827, a) bears a near resemblance, in point of size and hardiness, to the best of

the native breed of the Highlands of Scotland, and other hilly countries in the north of Europe. It is too small for the present two-horse ploughs; but few horses are equal to them for enduring fatigue on the road. "I well remember," says Culley, "one that I rode for many years, which, to the last, would have gone upon a pavement by choice, in preference to a softer road. (Observations on Live Stock, p. 55.)

6:45. The galloway (b), properly so called as being found chiefly in that province of Scotland, has now become very rare, the breed having been neglected from its unsuitability for agricultural purposes. Galloway is, however, used as a term for any horse between the pony size and the hack; and in this point of view is sufficiently numerous, and very commonly bred by small farmers on commons and wastes. The true galloway is somewhat larger than the Welsh horse, and is said to resemble the Spanish horses; there is also a tradition, that some of the latter, that had escaped from the fleet of the Armada, when driven to the coast of Galloway, were allowed to intermix with the native race. Such of this breed as have been preserved in any degree of purity are of a light bay or brown colour, with black legs, and are easily distinguished by the smallness of their head and neck, and the shape and很少 people in the Island, and these are the kind of horses everywhere used in those districts. (Culley on Live Stock, p. 57.) Since Culley's time much pains have been taken to improve the breed, and to reduce cultivation, fitted not only for heavy but for light work. It is an uncommon thing for a Suffolk stallion to father a foal of over 30c. The best of these stallions in England is at Woodbridge Lady-day fair, where Suffolk cart horses have been brought from 100l. to 150l., and one mare and her offspring a few years ago at this fair brought 100l. The figure (825) hardly does justice to the animal. (31)

and usually black, with wide heels; the back straight, but not prominent, and the space between them and the ribs short, the tail heavy, and well haired, the thighs meeting each other so near as to leave only a small groove for the tail to rest on. One most valuable property of this breed is, that they are remarkably true pullers, a restive horse being rarely found among them.

6:44. The Welsh horse (fig. 827, a) bears a near resemblance, in point of size and hardiness, to the best of

the native breed of the Highlands of Scotland, and other hilly countries in the north of Europe. It is too small for the present two-horse ploughs; but few horses are equal to them for enduring fatigue on the road. "I well remember," says Culley, "one that I rode for many years, which, to the last, would have gone upon a pavement by choice, in preference to a softer road. (Observations on Live Stock, p. 55.)

6:45. The galloway (b), properly so called as being found chiefly in that province of Scotland, has now become very rare, the breed having been neglected from its unsuitability for agricultural purposes. Galloway is, however, used as a term for any horse between the pony size and the hack; and in this point of view is sufficiently numerous, and very commonly bred by small farmers on commons and wastes. The true galloway is somewhat larger than the Welsh horse, and is said to resemble the Spanish horses; there is also a tradition, that some of the latter, that had escaped from the fleet of the Armada, when driven to the coast of Galloway, were allowed to intermix with the native race. Such of this breed as have been preserved in any degree of purity are of a light bay or brown colour, with black legs, and are easily distinguished by the smallness of their head and neck, and the shape and
resemblance to an eel stretched out. This very singular character subsists also in many of the horses of Norway, and is nowhere else known." (Walker's Hebrides, vol. ii. p. 158.) "The Highland horse is sometimes only nine, and seldom twelve hands high, except in some of the southern of the Hebrides, where the size has been raised to thirteen or fourteen hands by selection and better feeding. The best of this breed are handsomely shaped, have small legs, large manes, little neat heads, and are extremely active and hardy. The common colours are grey, bay, and black; the last is the favourite one." (General Report of Scotland, vol. iii. p. 176.)

Sect. II. Organology or exterior Anatomy of the Horse.

6247. A just knowledge of the exterior conformation of the horse, to be able to form a correct judgment on the relative qualities of the animal, forms the ne plus ultra of a scientific horseman's aim; but it is a branch of knowledge not to be obtained without much study and experience. In considering a horse exteriorly, his age, his condition, and other circumstances should be taken into the account; without which attention it is not possible to determine, with precision, the present or future state of a horse when he is seen under various peculiarities. A horse of five years old, though considered as full grown, yet experiences very considerable alterations of form after that period. He then becomes what is termed furnished; and all his points (i. e. his adult form), before hidden in the plumpness of youth, or disguised by extreme obesity, now show themselves. From the effects of muscular exertion promoting absorption, he becomes more angular, and to the painter's eye, would prove more picturesque, but less beautiful. A horse likewise low in flesh and condition, is hardly the same animal as one in full flesh and condition; and again, the sleekness acquired from relaxed labour, with full and gross feeding, is very unlike the robust form acquired from generous diet with correspondent exertion.

6248. The examination of the subject of organology is conveniently pursued by dividing it into head, neck, trunk, or body, and extremities or legs. The greater number of well proportioned horses, with the exception of the head and neck, come within a quadrangle; not one strictly equilateral as depicted by Lawrence (Richard) and Clark, but one whose horizontal dimensions are usually between a twenty-fourth and twenty-eighth greater than their perpendiculars. It must, however, be kept in mind, that with some considerable deviations from this quadrangular form, many horses have proved superiorly gifted in their powers; and that a deviation from these proportions appears in some instances, as in that of the race horse, not only favourable, but necessary also to his exertions. Nature will not be limited, and the perfection of her operations is not alone dependent on the arbitrary arrangement of parts, but on a harmony and accordance of the whole, internal as well as external. To the artist, however, such admeasurement is useful, inasmuch as it prevents any singular departure from a symmetrical appearance, which is but too common among our animal draughtsmen. To the amateur it also offers a convenient, though not an unerring guide. Our exemplification of the organology appears by placing a blood and a cart horse within the same square (fgs. 828.), by which the differences between the various parts of the one and the other are readily contrasted.

6249. The organs of the head. The head of the horse is remarkable for its dimensions, formed by an elongation of the jaws; yet in him, as in most of the grazing tribes, its bulk is in an inverse proportion to the length of the neck, otherwise the muscles would not be able to lift it. It is an important part considered as relative to beauty alone, it being in the inferior heavy breeds but little marked by grace or expression; but in the improved varieties it presents lines worthy the painter's pencil and the poet's fancy. Neither is it too much to say, that in no part of the body is this amelioration of breed so soon detected as in the head. Can any thing be conceived more dissimilar than the small ineffectual features of the cart horse, and the bold striking ones that grace the head of the blood horse? The quick succession of movements in his pointed ears, the dilatations of his expanded nostrils, or his retroverted eyes, which give fire and animation to the character of his head when under the influence of any excitement. This is the more worthy of remark, when it is considered that some of the principal aids to expression in the human countenance are wanting in the horse. Man borrows much of his facial expression from his eyebrows, and when to these the varied action of the mouth is added, it amounts to more than a half of the total expression. A great accession of beauty is gained in the improved breeds by the increase of the facial angle, which in them is about 25°, but in the heavy breeds is usually only 23° (a a a a).

6250. The ears (b b) in the improved breeds are small and pointed; in the heavy they are not only large and ill shaped, but they frequently separate from each other; these defects gave rise to the barbarous custom of cropping, now happily in a great measure abolished. The ears are criteria of the spirit, as well as of the temper; we have seldom seen a horse which carried one ear forward and the other backward during his work that was not hardy and lasting. Being not subject to early fatigue, he is attentive to everything around him, and directs his ears different ways to collect sound from every quarter. The ears are also indications of temper, and a horse is seldom either playful or vicious but his ears are laid flat on the neck. It is fortunate that we are provided with such a warning, by an animal that does not want craft to surprise us, nor strength to render his resentment terrible.
6251. The forehead next presents itself (c c), straight, and of a proper width in the improved breech, adorned by nature with an elegant portion of hair, which, detaching itself from the rest of the mane, flows down the face to protect both that and the ears from the attacks of insects.

6252. The eyes (d d) deserve particular attention, not only for their utility, but as objects of beauty and expression. In the blood horse the orbital fossae, or eye-sockets, are more prominent and more inclined, by which the axes of his eyes diverge more from each other than those of the heavy breed; by which not only he is enabled to see further behind him, but the prominence of his eyes gives great beauty and expression to the blood head. The further consideration of the eyes, and their criteria of soundness, will be postponed to the anatomical detail. In old horses most of the fat of the body, which is more superficially placed in the young, becomes absorbed; in this way the eye, which is usually embedded in a vast quantity of this matter, losing its assistance, sinks within its orbits, and thus the cavities above, called eye-pits, shows themselves deeply in an aged horse.

6253. From the cars to the angle of the jaws (e e) large vessels and extensive glands are situated. Within these branches of the posterior jaw is lodged the throat, and it will be observed how necessary it is that these branches should expand sufficiently to admit of the motions of the head, particularly of those influenced by the reining-in of the bridle; otherwise the blood-vessels and other parts must be injuriously pressed upon.

6254. The hollow between the jaws is called the channel, and at the under part of it (f f) a considerable branch of an artery proceeds from the inner side over and around the outer, which branch forms the most convenient situation for feeling the pulse of the horse.

6255. The face (g g) of the improved breed of horses presents either a straight line, or one slightly curved inward towards the lower part; whereas, in the heavy breeds, it is very commonly found to be curved outward. This part comprises, as with man, from the forehead to the lips. When the face is covered with white, it is considered a blemish; but when a white spot only exists in the forehead, it is considered a beauty.

6256. The markings in the face are useful to describe a horse by, and frequently lead to the recovery of a stray or stolen one. In regimental accounts these marks are carefully noted. When a spot extends down the face, it is termed a blaze; and when further continued into the muzzle, it is called blaze and snip. When a star is distinct, but with it there are white markings which begin some distance below it, and are continued downwards, it is called a race.

6257. The muzzle (h h) includes the lips, mouth, and nostrils; the darker the colour of this part the more is the horse esteemed; very dark brown horses are an exception, for in them it is usually of a tan colour, and is praised both as a beauty and indicative of excellence. It is both a beauty and an excellence that the nostrils be thin, angular, and large.

6258. The lips should be thin, firm, and by no means loose and pendulous, as is the case in the old and sluggish. The lips in the horse are the principal organs of touch and discrimination, and hence are exquisitely sensible.

6259. The form of the mouth, as receiving the bit, is important. It is also of more consequence than is usually supposed, that its commissure or opening be sufficiently deep; when shallow, it is not only inelegant, but it will not admit a bridle favourably into its proper resting place upon the bars. Within the mouth are situated the teeth, which are so placed as to have interrupted portions of jaw above and below of considerable extent. These vacancies are called bars, and are parts of extreme importance to the horseman, as it is by means of agents called bits resting on these parts, and operating on their sensibility by means of a lever, the long arm of which is in the hand of the rider, that he ensures obedience. In aid of this mechanism, to one portion of this lever is attached a chain, called a curb, which acting on the outer part of the chin, increases the pressure. This latter part has been called the barb or beard, but its situation is evidently above that.
ORGANOLOGY

The organs of the head are: the incisive and canine. The two front incisives are popularly called nippers or snares (a); the two next adjoining, separators or middle teeth (b); and the four at the corners (c). It would be more definite to say the first, second, and third incisives, beginning at the corner of the mouth, or those (d) occupy part of the intermaxillary space between the incisive and grinding teeth. The teeth, as criteria of age, will be considered in another place, and as organs of mastication, they will be further noticed in the anatomical detail.

625. The organs of the neck. The exterior parts which compose the neck are first the upper surface, which is furnished throughout its whole extent with an elegant assemblage of hair called mane (e). In some instances, as in stallions, it is of enormous length and thickness. In dark-coloured horses it is commonly black, but in horses of colours approaching to white a light hue is very frequently seen, and the mane and tail are in these often lighter than the body.

626. To make the hairs of the mane and tail lie smooth is an object with all horsemen, but the pulling of the hair, especially of the feathers, is a most mortifying practice, and not only at the time frustrates the end intended, but a mane so pulled will seldom hang well after. The common practice of white horses has always made use of a three-pronged angular mane-puller, which, if used two or three times a week, will bring the mane and tail into perfect order, and will keep them so. This iron is manufactured and sold by Long, væve and Son, 28, Cornhill, London.

627. The upper surface of the neck (i) should form a moderate but elegant curve, which is greatly favourable to beauty: this curve is, however, not so considerable in the pure eastern variety as in the better sort of northern horse.

628. The under surface of the neck (k, l) should be nearly straight; in the cock-hocked horse it arches outwards, and the upper surface in these instances is sometimes hollowed inwards in equal proportions, and the hollow in this case is called wese-necked. When this deformity is considerable, it prevents the head from being carried so naturally, and particularly so under the action of the bridle, as in the common case the nose being projected forwards, carries the axis of the eyes upwards: such horses are called star-gazers; and it is to be observed that they are seldom safe-goers. In mares and geldings a very just criterion is the slaggish disposition, made more considerable by the flesh on the upper surface of the neck: when the crest is very thick and heavy, it is almost an unerring prognostication of a decided sluggard. In stallions it, however, forms a distinctive sexual mark, and therefore is less to be depended on.

In a well-proportioned horse, the length of the neck, the length of the head, and of the angle uniting the two; these give the height of the forehead, the length of the neck, the length of the head, and the angle uniting them; the longer the neck is too short, the head must of course gravitate by the increased length of the arm of the balance; it likewise seldom presents a firm or proper resistance to the bridle. When, on the contrary, the neck is too short, the head is frequently ill placed, and the lever in the hand of the rider will be too short also.

629. The organs of the trunk or carcasse are various. Considered as a whole, Clark has not unaptly likened it, when separated from the limbs, to a boat; within which are disposed important viscera. The bony ribs he likens to the wooden ones encompassing the vessel, and the sternum or breast-bone, being perpendicularly deep and thin, carries the resemblance further, and fits the machine to cleave the air as the boat does the water. Within this animal vessel, according to the justest mechanical principles, the weightiest of the viscera, the liver, is placed in the centre, and the others follow nearly in the relative order of their gravity; so that the lungs, the lightest of the whole, are stowed in front, where great weight would have been most disadvantageous.

630. The shoulders (a, b, b) are commonly considered as extending from the withers above to the point in front, and to the highest point well forward for breadth; and considers them as those parts immediately concerned in motion; that is, the scapula or blade-bone, and its attachments. The shoulders are too apt to be confounded with the withers above, and with the arm below, erroneously called the point of the shoulders. From this confusion, great error is committed in appreciating their natural power and action; but this is of importance in reference to the parts (fig. 626, k l f). The relative parts must be justly proportioned at the same time that the shoulders may be narrow, straight, and altogether body formed, and \\n
The shoulders should be muscular and narrow, but not heavy; and to determine between these essential points, requires the eye of experience in the viewer, and the presence of condition in the viewed. A muscular shoulder is essentially necessary, when we consider that the extremities are wholly connected by muscle, and not as in man, by the intervention of the bony union of the clavicle or collar bone. In the horse, therefore, we find that large muscular masses unite the shoulder blade, by its upper and inner surfaces, to the chest; while other powerful muscles suspend as it were the machine between them. By this contrivance, elasticity is preserved and strength gained; for had the shoulders possessed a bony connection, when the body is propell'd forwards, its weight and force being received by the fore extremities, painful and hurtful shocks would have been experienced at every step. Powerful muscles for the shoulders are also as necessary for progression as for attachment. It is not therefore with judgment that a very thin meagre shoulder is commonly preferred. It is by the union of strength with just proportions, and a proper situation of the parts, that the value of the animal is determin'd.

631. The centre of action in the shoulders (c) is in their common centre, and the extent of action of any part moving on its centre, is dependent on the length of such part; the motion the shoulder enjoys is opposed to an upward and perpendicular, and they take part of forwards. It will be therefore evident that the more oblique is the situation of the shoulder blade, the greater number of degrees it can go through; it must be as evident also that when the shoulder blade is long and deep, as well as oblique, that this advantage is increased. It is commonly observed, although it is not universally the case, that the shoulder is short, it is of an upright, (h) Oblignity and length in the shoulder favour the safety of the progression also: for as the angles formed between the shoulder, the arm, and fore-arm, are constant and amazing, and make, when in action, a bony arch; so the obliquity and length of the shoulder is conducive to a due elevation of the limb, in which the great degree, depends the safety of progression. Thus maries are, oetesis paribus, more unsafe than horses, their shoulders being short to correspond with the low mare-like forehand; and their decreased obliquity usually regulates an increased obliquity in the whole limb downwards, or as is familiarly expressed, they stand in a certain degree on each other's hind leg. For this form of the body, both for the use of the forehand and of their action, it was given for advantageous purposes: for, by such a position in the fore extremities, the hinder are raised higher to afford additional security against the evils of gravitation and dislocation of the foal from the pelvis. Four rules can be laid down in the exterior conformation that are of importance or of such general application, as that a short and upright shoulder, particularly when united with an
inclined direction of the whole limb backwards, is a sure mark of an unsafe gait, and commonly, though not invariably, of a slow one also. It now and then happens indeed, that horses having defective shoulders propor-tioned in a certain degree, appear to be inclined in the same direction on their axis, but would appear to do so from the effect of their legs, and it is possible that, wherever horses having these defects in their fore legs yet prove quick and safe in progression, they invariably have hinder parts of great strength and proportion to make up the deficiency. Indeed, it appears that the hand and fore legs of the horses do not excite the action of the back in blood horses, the withers are not always high, and although their shoulders are commonly deep and oblique, yet the fore limbs are altogether short in proportion to the hinder, in a great number of the fleeted racers: for, as speed appears to be a principal end of their creation, and as comparative anatomy furnishes too little room to make a closer destination of all the defects destined to make comfortable all animals designed to be capable of answering the most nothing more than a succession of leaps are low before, the end of their formation is really best answered by this arrangement of parts; it is also more probable that, although speed in the gallop may be the chief object, the showhorse is formed, yet, in the run, the hind formed shoulder is more immediately requisite. This subject will be still further elucidated when we treat on the mechanical properties of the skeleton.

658. The withers (c. e.) are formed by the long transverse processes of the dorsal vertebrae (fig. 850, p), and the power of these joints is to serve as levers to muscles, so their length characterised by the height of the withers must be of great advantage, and enable such horses to go high above their ground; for the muscles of the back, acting to greater advantage, elevate the fore parts more forcibly. From this we may also learn that the elevation of the fore parts, or the horse's going above his ground, as elevation is the part altogether dependent on the motion of the shoulders, nor on the height to which the animal may be inclined to lift merely his legs; but likewise, on the extent to which the fore half of the machine is altogeth-er elevated by the action of the dorsal and lumbar muscles. When the withers are high, or the forehand well up, as it is termed, it is favourable for the velocity and the safety of the action; but as these properties are less prominent in the heavy breeds, we find in them a considerable variation of form: in the cart horse, weight of forehand is an essential requisite to his exertions; for drawing being an effect of the animal's own motion, it is natural that his whole energy should be concentrated in this centre, the more advantageously he will apply his powers. It is not here intended to be hinted that nature cannot make such contrivance; but in the horse, the forehand is a necessary part of the production, but this form has been judiciously imposed on him by men, by regulation of the sexual intercourses, and by a careful selection of specimens having some of the requisite to propagate from, until at last we have produced the massive weighty animal whose powers astonish as well as benefit us.

659. The action of the counter (f. e) is to support the part between the shoulders, and which should be moderately wide and extended: when it is otherwise, the horse is seldom durable, or even strong, although he may be speedy: neither have the lungs sufficient room for expansion, nor the surface of attachment, but it is frequently too much, where the build is of circular form in the carcass in general; all which experience has shown to be necessary to the perfection of the machine. The breast may, however, be too wide: it may also hang over or project beyond the perpendicular of the fore limbs, so as to overweigh the machine: this form, however, though unfavourable to the saddle horse, for the reasons just assigned, is much desired in the heavy draught horse.

670. The back. Where the withers end the back commences (g): the length should be moderate only, for the back cannot be so long as one of less length at the point of action and the rection are considerable; but what is gained in elasticity is lost in strength. While the back is too short, the extremities are so much approximated that they frequently overreach each other, and the hind foot strikes that before it, in progression; the back should be nearly straight, it has naturally no curve along its line of gait; but this is not always the case; when the in-currence inwards is considerable, such horses are called saddle-backed, and are usually considered weak, but, to keep up the counterpoise, the crest in such horses is generally good: they also ride pleasantly, and commonly carry much apparent carcass; sometimes indeed too much. When the back is curved upwards, it is called reach-backed: when considerably so, it is unfavourable to the liberty of action, as well as to the elasticity of motion: in these cases, to counteract the curve outward, the head is also usually carried low. A short-backed horse is in considerable request with many persons, who do not consider it is too much: it is termed a great speed; for the hinder extremities cannot be brought sufficiently under the body to prop the mass forwards.

671. The loins (b) may be considered as the part which extends from immediately behind the hinder edge of the withers, when properly defined, to the rumen; fig. 850, n. In which processes being sometimes defective or interrupted, leave an indentation, as though the union between the back and loins were incomplete; and such horses are said to be badly joined: but although it may be in some measure deprive the muscles of some slight attachments, the evil is not so considerable as is generally assumed, because the width of the loins is of considerable advantage in forming a greater surface for the attachment of the powerful muscles of the back and loins; and the muscles themselves should be so proportionate, as to seem to swallow the back bone amongst them. When the pro-portioning of the ilium or haunch bone are very prominent, the horse is said to be rugged hipped; but it operates to his disadvantage only in appearance, as extent in these parts, being favourable to muscular attachment, is always beneficial.

672. The croup (n) extends from the loins to the setting on of the tail (n). It should be long and only slightly rounded, which is another characteristic of the blood or improved breed. In the cart horse, on the contrary, it is seen short and much more considerably rounded (n). A long croup is in every point of view the most perfect, for it affords a very increased surface for muscular attachment, and although the tail of the cart horse should at first sight appear useless, yet, attentively viewed, it will be found that the early rounding of the sacral line, the low setting on of the tail, and the small space which necessarily exists between the hips and buttocks, all tend to lessen the surface of muscular attachment, compared with the broad croup, wide haunches, and deep spread thighs of the blood horse.

673. The flank (k), is the space contained between the ribs and haunches; when too extensive it in-dicates weakness, because it is the consequence of too long a back: and such a horse is said not to be well ribbed up. When the transverse processes of the lumbar vertebrae are shapely in a badly joined horse, this part is hollow. The flank is usually looked to also as indicative of the state of respiration: thus, when it rises and falls quicker than ordinary, unless violent exertion has just been used, it betokens pre-cocity, and consequently the shortness of the lungs.

674. The belly (t). Having taken a tour round the upper parts of the carcass, we will carry the survey downwards and forwards. Anteriorly, the ribs should be wide upwards, and as much deepened below as possible, which affords what is termed great depth in the girth. This form greatly increases the surface of the respiratory organs, and also of the motive organs of the muscles, and consequently is favourable to the wind. Posteriorly, the ribs should form the body as much as possible into a circular figure, that being of all others the most extended, and affording the best surface for the respiratory organs; this is especially true of the terrified horses, these horses are greatly esteemed, and found to be lasting in work and readily brought into condition, and more easily kept up. When the chest is too flat and straight, the belly is also small: hence, neither can the blood absorb its vital principle from the air, nor the lachrymals the chyliferous juices from the intestines; these horses are therefore seldom durable. As less instrument is taken up by the constitution, so less is eaten, thus also they are seldom good feeders;
and the pressure on the intercostals may be considerable from the small containing surface, so that they are usually likened to what is termed washy; that is, easily purged, with an additional outflow, from the too early passing off of the food. Such horses, are, however, very commonly spirited and lively, although not lasting. A knowledge of the advantages gained by a circular form of carcass or body, and the caudal conformation of the stomach and the rectum, is secret in the breeding of cattle: he always bred from such animals as would be most likely to produce this form, well knowing that no other would often so advantageously.

6253. The shirrbone (l), among the jockeys and grooms, is the articulation of the thigh bone, with the posterior part of the thigh; it is one of the principal points of injury, and can only be resisted by the strength of the observer, and the force of his admission is essential to the safety of the part. No bandage is the situation of the thigh (l, m) is in the horse, as in most quadrupeds, enclosed within the range of the trunk.

6277. The fore extremities or legs.

In treating of the mechanical properties of the skeleton, we shall have to point out the essential differences between the geometrical structure and functions of the fore and hinder extremities. We shall here content ourselves with a simple examination of the individual parts.

6278. The arm of the horse (d) is apt to be overlooked, nor, without some consideration, does it strike the observer, that the arm covered with muscles, and enveloped within the common skin of the chest, extends from the elbow (a) to the point of the shoulder, as it is termed, but correctly to its own point below and before the shoulder blade. (fig. 830.) The same reasons which render a muscular, oblique, and deep shoulder, essential to the horse, this part should be muscular that the joint should be firm, strong, and as tenacious, and breadth, and that its obliquity should be proportionate to that of the shoulder: whereas it results, that the more acute the angle between the limbs, the greater will be the extent of the motion gained by the flexion in the direction of the parts.

6279. The fore arm (c), which horsemen consider and call the arm, is placed upright to counteract the angular position of the real arm and shoulder bones. As it is always found long in animals destined for great speed, as we witness in the hare and greyhound, it should therefore be of considerable length "in proportion to the weight of the animal, and the more so for the cæcum, a part of the stomach, which is required to be distributed equally through all parts of the limb, it is chosen short. The fore-arm is broad and large, particularly upwards, for here the powerful muscles that operate the motions of the parts below, the influence of the incumbrance, the steadiness of the animal, these muscles degenerate into tendons and ligaments below the fore-arm; but above, it is essentially necessary to strength that they should be large and well marked.

6280. The knee (d), so called, is properly, with reference to human anatomy, the carpus or wrist. It is enveloped within well-bred limbs from the jarring arising from the concave nature of the perpendicular part above and below it. All the joints of the extremities, but particularly those of the knee and hock, should be broad, that the surface of contact may be increased, and the stability augmented; by this means, likewise, a more effective, more extensive adhesive attachment is applied to muscles and ligaments; their insertions are also thereby removed farther from the centre of motion.

6281. As criteria of safe going, the knees should be particularly examined when it is contemplated to purchase a horse, to see whether the skin has been broken by falls; and in this, very minute attention is required to judge of some points. According to the form perfectly, or otherwise so much art is used in shaving the hair, blistering, colouring, and rubbing it down, picking out the white or staring hairs, &c., that more than common nicety is required to detect a slight scar. It is, however, prudent to remember, that it is not every horse whose knees betrays a scar, that is a stubber: the best may have a fall in the dark. It is also necessary to caution persons against the admission of a very common prejudice, that when a horse has once been down, however little he may have hurt his knees, he is rendered more liable than before to a similar accident. If his limbs have not been weakened by the accident, or if the cæcum be not sufficiently padded, and a horse, he is not a more liable to the knee than to any other part of the horse. If, therefore, a horse with a scar on his knee have the foreshoal good, and if his action correspond thereto, he ought not to be refused on this ground: but with a different consideration, he ought to be steadily rejected. The scars of gross heavy horses a scabby eruption often seats itself around the inner bend of the knee (b), which is called malleniers.

6282. The canon or shank (c) carries the limb down elegant, light, straight, and strong. Much stress is deservedly laid on the necessity that this part of the limb should be wide when viewed laterally. Viewed from the quick, the bone and limb are seen to be so extended to it beyond these must arise from useless cellular matter, or otherwise from matter worse than useless, being placed there by disease. Any thickening of the part generally or partially, should be looked on with suspicion; if natural, likely to interfere with motion without adding to strength; or if accidental, as a mark of acquired injury likely to remain. In the buoy skeleton may be seen within and behind the knee an apparatus destined to remove the acting ligaments and tendons from the centre of motion, by which great advantage is gained in strengthening and facilitating their flexions. It is a defect in this construction that renders horses fixed. (fig. 831.) knee, as it is usually termed. The limb below the knee, instead of proceeding downwards of a uniform width, is seen suddenly narrowing immediately as it leaves the knee. Such horses are invariably found to bear exertion badly; their legs at an early period become bowed and affixed to the thigh; if the limb is fixed, the strain is transmitted through the arm, and the bone and hand will yield readily to less force. Excess of, the same happens to the ligaments and tendons called back sinews which flex or tend the fore legs; for by apparatus, formed in the junction of one of the carpal bones (pisiformis), they are, in well formed legs, set out wide from the knee.

6283. The back sinews should not only be wide and firm, but they should, like the limb generally, be very well filled up, as is principally true of the back sinews, even in the horse, if any thing, a part of the body is chiefly subject to injury, as extension or rupture of ligamentous fibres, which usually have a disposition to recurring weakness. If a hard swelling appear on the inner side, not on the tendon, but on the bone, a splint is present which is a mark of more or less injurious as it is nearer or farther from the knee, on the bone: if it is close to the bone, and the tendons and ligaments are palpable in the horse, it is overfed, and extends inwards and backwards among them, it usually produces most injurious consequences. To detect these evils the eye alone should not be trusted, particularly where there is much hair on the legs, as on cart horses, and even on hackneys in the winter, but the hand should be deliberately passed down the shank before and behind. An enlargement or scar situated close to and on the inner side of the knee, must not be mistaken for a splint; it more frequently arises from a custom some horses have when trotting fast, of elevating their feet and cutting this part with their shoes, and it is thence called the speciose cut.
628. The pastern and fetlock (f. f.). General usage has applied the term fetlock to the joint itself, and pastern to the part extending from the fetlock to the foot; properly speaking, the fetlock or footlock is only the posterior part of the joint, whence grows the lock or portion of hair, which, in many horses, however, is commonly neglected; a joint at the hinder end of the foot is found in most horses; they are uneasy goers; they are unsafe also, for the pastern being already in so upright a position, requires but little resistance, or only a slight shock, to bring it forwards beyond the perpendicular; and the weight of the machine then forces the animal down. Nor can it ever easily revolve. Notwithstanding the formation of the bony part of the fetlock is exposed to contact with each other in a nearly perpendicular direction, receive at each movement a jar or shock, which leads to an early derangement of the joint, and to the appearance called overshot. On the contrary, when the pasterns are too long they are frequently too oblique also, and give an oblique direction to the stirrup, which is displeasing to the horse, as it hinders the passage of the limb. These joints both before and behind are very subject to what is called wind-galls, which are swellings formerly supposed full of air, whence their name; but they are now known to contain an increased secretion, to which the defects are due. The swellings or tumours are originally small and hidden between the lower end of the cannon and the flexor tendon, or back sinew; but when hard work has inflamed all the parts, the secretion within increases, and then they become visible to the eye; but unless they are so considerably as to obstruct the due action of the parts, they are no otherwise objectionable than as they tell a tale of inordinate wear of the limbs generally.

629. The form of the pasterns influences the defect called cutting, which arises from a blow given to either the fore or hind fetlocks by one leg to the other during its evolution. Horses narrow in the crest, or which turn their toes out, or have other peculiarities of form, cut permanently, and are then very objectionable; but others only cut when fatigued, or when very low in flesh. Horses often cut when young, who leave it off when furnished, and of mature growth.

630. The feet (g.). These essential and complex organs will be more fully examined in the anatomical detail, but much also presents itself to the consideration in an exterior examination. Horses might be presumed to be naturally born with perfect feet; but experience shows that defects in these organs are here and there; and that a peculiar operation on the parts of others, a constitutional predisposition exists; dependent on some cause with which we are unacquainted.

631. Climate influences the form of the horse's foot. In the arid plains of the east, where every impediment to an extensive search for food is removed, the feet are hard, dry, and small; this form, noted especially in the south of America and in India, becomes to the eastern horse: artificial habits have extended the evil, and now small and contracted feet are seen in every variety, except in the coarse heavy breeds.

632. Constitutional and hereditary causes operate on the foot. That a constitutional predisposition exists in the production of a particular form of foot, we know from the fact, that dark chestnut horses are more prone to contraction of the hoofs than any other coloured horse; and that the form of the foot is hereditary, may be gained from the known circumstance that some of the Lincolnshire stallions always have large flat-footed progeny; while some full bred entire horses entail small upright feet on all their offspring.

633. Local situation will also affect the form of the foot. The effect of situation is remarkably exemplified in opposite forms which we obtain from the sand dunes of Norfolk and Yorkshire, before the draining system was perfected. These horses had, almost invariably, large, flat, heavy feet; which, however convenient and natural they might prove to the animals while moving on the quaggy surface of marshy districts, yet were found very unfit for quick light movements in the field. Such horses stumble. Heavy and stiff, the feet are formed is always weak, the anterior or front part yields to the heat and inflammation brought on by exercise on hard roads, and falls inwards, which letting the weight of the body fall on the sole pushes it downwards; and at last from a concave, it presents a convex character. The feet cannot then bear shoeing, but with much art and difficulty: pain and tenderness bring on lameness and uselessness; and therefore horses with such feet should be rejected. Feet preternaturally small are equally objectionable, as being a disqualification to croft, Bosting a disposition to contraction, horses with a tendency to founted feet stand with pain in their backs. When, placing one foot before the other, and then shifting their feet, the contraction usually begins in the heels, which are found higher than natural, and drawn inwards; the foot altogether is likewise narrower, and the sole hard and hollow. When a preternatural fullness is seen on the crown, ring-dent, these horns may be suspected to be affected with anything in going, its existence is certain. But although too much horn is to be avoided, too little produces a weak foot, in which the heels, quarters, and soles all participate: the thin horn cannot resist the impressions of the stones on the road, and then lameness ensues. The under surface of the foot should be healthy, wide, firm, and prominent, with hard paces; the side should partly be particularly attended to; when less than natural, it is weak, when more it indicates contraction; whence such feet have been called too strong. White feet are objectionable, because they are found more liable to this evil than others. Corns are an evil to this, and when under the surface of the foot, is liable, and which should always be looked for on the purchase or examination of a horse; for which purpose, it would be well that the fore shoes should be removed, and the foot carefully pared by a judicious and clever smith. Merely picking out the foot will often, also, detect the remains of former cuttings or jarring out of the corus. Some hobs are very brittle, and a horse with this defect should, in every instance, be rejected. The evil may in general be easily detected by the marks of the fragile parts detached themselves from every nail-hole. This kind of foot, particularly in hot weather, breaks away till the edge of the fore horse becomes shorter; and part is the foot is another evil to which the feet are liable; and which should engage the attention in the examination of a horse: they consist of longitudinal fissures; one only is usually present at once; but that one if deep is fully prejudicial to the animal. The subject of the feet was examined by an excellent observer of animal situations, with regard to their general appearance, well worthy of our attention. The eye should be directed to the three, and to the manner in which the shoes are worn; which will often save much useless trouble in trying a horse. A stumbling horse may be frequently, nay, commonly, detected by simply lifting up one fore foot: for the unequal weight of the body of the shoe at the toe, while the other parts remain good, is a full proof of his going unsafely and digging his toes.

634. On a review of the configuration of the foot extremities, it may be remarked, that whereas the hind limbs are concerned as much as the fore limbs, particularly concerning the requisite velocity; yet, that upon a proper form and a true direction of the various component parts of the fore limbs must depend the stability, the truth, and the safety of the movements. Viewed anteriorly, the fore legs should stand rather wide at the upper part, inclining a little inwards below; but when we view the hind legs, it appears that they should present their perpendicular to the line of direct course it is to be followed in a direct line downwards; he generally inherits these desirable properties. When the foot stands behind the perpendicular line the defect is considerable, by the removal of the centre of gravity too much forward, by which an increased tendency to stumble and fall is obtained; and as this in general accompanies a want of extent and obliquity in the shoulder, so it likewise lessens the speed.

6291. The hinder extremities. We have already described the thigh, correctly so
called, which is so concealed by muscles as frequently to escape this consideration of it, by which the part immediately below it popularly receives the name of thigh, but which is

6292. The leg (1, 2), commonly called the Thigh, in well formed horses is powerfully furnished with muscles, and has very considerable power in its figure; it should also make a considerable angle with the hip, and form a direct line under the hip or hock; for the same reasons that make it desirable to have a long arm in the fore extremities, it is also advantageous that the leg should be so likewise, and this is the case remarkably among all quadrupeds.

6293. The hock (3) is the important joint immediately below the leg, or thigh commonly so called, and is interposed between the tibia and tarsal bones (fig. 830), purposely to increase the extent of attachment, and to break the shock of great exertion; it may be considered as the most complex and important joint of the body, and broad; for, in considering the muscle, ligament, and bone attachments, of the hock (5), and which is the real heel, extends itself beyond the other bones, so the powerful tendo Achilles inserted into it, acts with a longer lever, and with a greater increase of power. This joint is subject to many serious consequences, from the want of a corresponding enlargement of the windgalls before mentioned, and what has been said on them equally applies to these. When similar mucous capsules become enlarged on either side, and are supposed to have the name of then bursae, the same remarks apply.

6294. The colour of horses does not depend on their real skin, as with man, but upon an exterior beautiful covering which nature has given them, called hair; nevertheless, the hair is, in some measure, influenced by the skin, as light-skinned horses have light hair, and when the hair is light, the eyes are usually so likewise: hair presents many varieties of tint, so horses are said to be of various colours. Buffon has conjectured that horses were originally of one colour, which he presumes to be bay; but such wild horses as have been seen, and which have been supposed to be pure originals, have not justified this opinion. This same author has divided the colours of the horse into simple, compound, and strange or extraordinary.

6295. The simple colours are bay, chestnut, dun, sorrel, white, and black; bay is a very prevailing tint among European horses, and admits of many shades, but is admired in all; there are bright bays, blood bays, dark and dappled bays; brown bay is a very esteemed colour, and consists of bay and black in unequal proportions, or is a mixture of the different tints, the lighter varieties have usually beautiful tan markings, as about the muzzle, &c.: they have commonly also black manes and tails, with legs and feet of the same hue; and it may be here remarked, that horses of compounded colours, of whatsoever tint the mane and tail may be, will be found invariably formed of one of the compounding colours; thus light greys, which are a compound of black and white, have often white manes and tails; sorrels, again, which are formed of white, with a small proportion of red, have also frequently white manes and tails; chestnut, which is also a very common colour, admits of almost as many shades as the bay, frequently with a very light chestnut, or dappled, and frequently with a strong chestnut, or dappled with black manes and tails, with mealy legs and light feet; so marked, they are certainly not to be chosen for strength, durability, or pliability of temper; the Suffolk punch, however, may be considered in some degree an exception to this, as he is thought to be capable of enduring fatigue better than most horses. Dark chestnuts are never considered, and with justice, as fitly disposed; they are also more subject to contracted feet than horses of any other hue. Dun is a colour that has several varieties; it is sometimes accompanied with a white mane and tail, at others they are seen darker than the rest of the horse. In some, a list or line of white hair extends down the back, which is regarded by some as a drawback and disqualification in the bay. A dun horse does not appear to be at all influenced in their qualities by their colour, or rather no criteria are offered by it, for there are good, bad, and indifferent in all the varieties of shade. The sorrel is a variety of the chestnut, but not a favourite one. White as a native colour is not in much estimation, neither is it very common, for many horses are white only through age, and as all light-greys and flea-bitten horses become so. Black is a very usual colour, and in the large heavy northern breeds it seems to be an original tint; and perhaps it is to this their goodness may be attributed, for among the lighter breeds, there are many indifferent black horses than of any other colour. The tempor of black horses are commonly in the extreme, either sluggish to stupidity, or fiery to excess. The colour itself admits of many shades; but a perfect black horse is more unusual than it is generally thought to be; and is consequently esteemed the elon hue; a black horse is often subject to the greatest diseases of the skin, as the hairs on the breast frequently interrupt the uniformity. It is, perhaps, on this principle that black horses have white legs so often as do.

6296. The compound colours may be considered as those in which the hairs are compounded, but not the colours themselves; otherwise the bay, the chestnut, brown, &c. might be considered as compounded colour. The roan is a mixture of red and white: its varieties are the common, the red, and the dark All the roans are esteemed. Grey admits of a great number of shades and varieties, and all are commonly considered very handsome; grey receives the name of bay hair, and a black; a considerable prejudice exists in favour of this colour. Greys are light or dark; there are also the dappled, the markings of which are extremely beautiful, and the silver grey. Grey horses become lighter, from grey until age overtake them. Grey and black, are well mixed and considered of no settled character; though, unlike them, they are not to be generally disapproved of. They have, however, all the extremes within their range; the darker ones are usually good, the lighter ones not generally so.

6297. The extraordinary colours are not very numerous, and it may be remarked, that white is always the relieving tint, intermixed with distinct markings, in various proportions, of bay, brown, black, or chestnut. Flea-bitten is grey or white, with small bay spots. When these spots are very large, and have a marginal surface of lighter markings, they give the name tiger coloured; and although not common with us, they are not unfrequent in Germany and Bavary. Piebald or pie-bald is one of the most numerous extraordinary colours, and is usually composed of two colours, in distinct large markings.
PRACTICE but within and but Undue peculiar and a bony beaut
Now quickens caverns sure branous whereas the observance of the bone is grinding each the
ing of the membrane. fact

6299. All quadrupeds are formed on an earthly base called bone, and the assemblage of
bony parts is called a skeleton. Bones are formed of earth and membrane (1881.); they are
covered also by an investure called periosteum. The earthly part is the last formed, and
consolidates the bones as the animal becomes fitted to exert all his powers. This deposit of
earth in the bones appears to be hastened by any thing that permanently quickens the circulation: heat does this, and hence the human and brute inhabitants of warm climates come to perfection sooner than those of northern regions; but they are
generally smaller, for by pretternaturally hastening the earthly deposit before the mem-
branous part of the bones becomes fully evolved or grown, they do not attain the bulk
they would be otherwise capable of. Undue exertion has the same effect; and thus we
learn why horses too early and too hard worked become stunted in their growth. Pressure
likewise occasions an early, and also a pretternatural ossification; in this way the parts of
the spine which bear heavy loads present large masses of bone, brought on by this
cause alone. For the same reasons, horses early worked put out splints, spavins, and
bony other concretions. Bones are all of them more or less hollow: within their
caverns an oily fluid is secreted, called medulla or marrow, which serves for their support,
and of the constitution generally. The bones have nerves, blood-vessels, and
absorbs. Bones are capable of reproduction, as proved by their uniting when broken; and
also by the yearly renewal of the antlers of the deer, which are not born as in the ox or
sheep, but pure bone. Bones are connected together by articulation: when such
articulation is moveable, it is termed a joint. In some cases bones articulate by suture
or indentation of parts, as in the skull. We shall consider, in succession, the anatomy of
the head, trunk, and extremities.

SUBSECTION I. Osseous Structure of the Head.

6300. The bones of the head are as follows. The occipital (fig. 839, between a & b, which is the largest
bone of the skull, in the colt is composed of several pieces which unite by age; it articulates with the atlas (a)
or first of the cervical or neck vertebrae. At its posterior surface it is perforated by a large hole, which gives
passage to the spinal marrow. The two frontal bones (b) unite also by age; and behind them is lodged the
sinus sphenoidalis, the inferior portion of the sphenoid bone of the brain. A division of the sphenoid bone
forms two cavities, called the frontal sinuses, which are lined by the nasal membrane throughout. The sagittal suture unites these
two bones. The remainder of the bones of the skull are the two parietals, the two temporals, divided into
each bone, and so the pontine, or inner, and the two postaural or turbinated bones, with the naso and phascolares, make up the
remaining facial bones, with the exception of the posterior maxillary or lower jaw bone (f), which on its
anterior angle is formed to lodge the teeth; at the upper part it extends itself into two angular branches,
the inferior or internasal bone (c) are the largest of the face bones, and contain all the upper molar teeth
The inferior or internasal bones (d) are wanting in man, in whom the face is short: these bones concur with the former in forming
sockets or sockets for lodging the teeth. The superior palatines, the inferior palatines, the pterygoids, the
maxillary, and the two posterior or turbinate bones, with the naso or phascolares, make up the
remaining facial bones, with the exception of the posterior maxillary or lower jaw bone (f), which on its
anterior edge is formed to lodge the teeth; at the upper part it extends itself into two angular branches,
the inferior or internasal bone (c) are the largest of the face bones, and contain all the upper molar teeth
The inferior or internasal bone (d) are wanting in man, in whom the face is short: these bones concur with the former in forming

Book VII. ANATOMY OF THE HORSE.

963

20. Four grinders, which numbers are equally divided between the two jaws. The teeth are inserted into indentations or sockets between the bone plates of the jaw, called alveoli, by cone-like roots. The bodies of the teeth are principally composed of two substances, one of the nature of common bone, giving bulk and form, and one of extreme hardness, called enamel, placed in man and carnivorous animals wholly

830

without the teeth, to give strength and durability; but in the horse and other Granivora, the latter particularly, it is placed in the grinders, in perpendicular plates, within the body of the teeth; by which contrivance, a rough grinding surface is kept up; for the mere bony parts wearing faster than the lamellas of enamel, it follows that ridges remain to triturate the vegetable matter that passes between the teeth.

6363. There are two sets of teeth, a temporary or milk set, and a permanent or adult set, in which wise provision man and most brutes participate. The milk set are some of them, as the molars, apparent at birth; there being usually six grinders in each jaw, three on each side in the new-born foal, and which number of this set is never increased. The nippers begin to appear soon after birth, and follow a regular order of succession until the animal is three or four months old; at which time he begins to require support from herbage as well as milk. The temporary set remove gradually one after another; had they all been displaced at the same time, or even had several of them fallen out together, the animal must have suffered great inconvenience, and perhaps have been starved. This removal, which commences at the age of two years and a half, and is completed between the fourth and fifth year, is effected by the action of the absorbents on their fangs, and appears to be occasioned by the stimulus of the pressure received from the growing teeth under them. For although these two sets appear with an interval of some years between them; yet the rudiments of both are formed at nearly the same period, and both sets may be thus seen in a dissected jaw. Regulated by the stimulus of necessity, as soon as the temporary set falls out, the permanent appears; and that such appearance follows the necessity is evident; for a premature or accidental removal of the colt's teeth is soon followed by the appearance of the others. Dealers and breeders, aware of this, draw the milk teeth to make their colts appear as horses. It was necessary there should be two sets of teeth; for, as they grow slowly in proportion to the jaws, had there been but one only, the disproportion of growth between the teeth and jaws must have separated them.

6364. The forms of the teeth vary more than their structure. The incise or nippers are round, which is favourable for the pressure they undergo; the upper more so than the lower. On the upper surface a hollow is seen in the young teeth, which, not extending through the whole substance, naturally wears out with the wear of the tooth; and as a considerable degree of regularity occurs in this wearing away in all horses, it has gradually settled into the general criterion of age. The nippers are not all of them exactly similar; the corner teeth differ most in being nearly triangular, and in having an internal wall or side, which does not become level with the rest until long after those of the others. The cuspidate tusks or terrors are permanent, appearing at about five years or rather earlier; those in the front jaw are usually nearer the nippers than those below. Each presents a slight curve, which follows the direction of all the canine or pugnatory teeth of other Mammalia. The pointed extremity wears away by age, leaving merely a buttoned process, which may serve as a guide to the age when a horse is suspected to be Bishoped, as it is called, from a man of that name who was peculiarly dexterous in imitating on old teeth the distinctive cavity of youth. The molar or grinding teeth are stronger in the upper than in the lower jaw; which was necessary as they form the fixed point in the process of grinding. The upper surface presents nearly a long square, indented from the alteration of the enamel with the bony portions; and as the interior or upper teeth hang over the posterior, so the ridges of the one set are received into the depressions of the other.

6365. Wear of the teeth. The teeth, in a state of nature, would probably present a surface opposed to each other for mastication, to the latest period of the most protracted life; but the removal of the animal from moist food to that which is hard and dry, must occasion an unnatural wear in those organs; and hence, although the teeth of the horse, even in a domesticated state, are not subject to the caries of the human; yet the grinders are liable to become thus injured by continued exertion. In the young or adult horse, the upper and under grinders do not meet each other horizontally; on the contrary, they have naturally an inclination obliquely inwards; and those of the upper jaw present small spaces between each other, while those of the lower are more continuous; by which means, as the food, particularly its interrupted portions, as grain, becomes ground, it falls within the mouth to be replaced under the grinding sur-
face, if necessary, by the joint action of the tongue and muscles of the cheek. This arrangement becomes in a great measure frustrated in old horses, by the superior wear of the inner surface of the upper grinders, as well as by the general misapplication of the surface of the teeth in such an upper and under teeth, that the more fortunate animal feels sensible of this, and endeavours to remedy it by throwing the wear on the outer edge, by an inclination of the lower jaw and of the head in general; and which is so particular in its appearance as to engage the attention of the horse dealer. But this defect may be prevented by a considerable difference in the size of the mouth, which is opened and wedged the mouth so as to keep it so, removing the inequalities with a well tempered con- 

evate, as much as may be. When the defect is considerable, and the horse is mild and quiet, it is better to file the inequalities every day, which will gradually but effectually wear them down. It however happens, that the improvements in the use of wear is so gradually increased, and the gradually the loss of nutriment takes place: in which case, soft moist food, as carrots, mash, soiling, or grazing, must be substituted for harder substances, and if corn be actually necessary, let it be bruised. Whenever an old horse begins to wear in this manner, his teeth, when he has them well wedged, and are far from being hard, their being neither bit nor carefuUy fitted, and the animal excited by fear, the teeth must be examined carefully. This undue wearing of the teeth occasions another evil often, which is ulceration of the cheeks, by reason of the projecting ragged surface of the uneven teeth, which can only be remedied by the removal of such portions. These projecting portions are called by farriers wolves' teeth.

Subsect. 2. Bony Anatomy of the Trunk.

6306. The trunk of the skeleton consists of the spine, the pelvis, and the thorax or chest, composed of the ribs and sternum.

6307. The bony column called the spine is made up of seven cervical, eighteen dorsal, six lumbar, and five sacral vertebrae, with the addition of thirteen or fourteen small tail-bones. The ribs are three pair; the lower pair of them are the smallest; the middle pair of them are the medium, however, some characteristics in common. Each is composed of a spongy bony body, with protruded points called processes, which processes unite, to form a hollow through which the spinal marrow is transmitted; and by some of these processes the vessels and nerves are articulated, as well as with each other, as with the vertebrae of the column in each the first and second differ from the rest in figure, and present some other peculiarities. The first is the only one of them to which the great suspensory ligament of the neck does not attach itself, which would have interfered with freedom of motion. It articulates with the second by receiving its tubular process within it, and from which process the second of these bones has been called dentata. Between these two neck bones is situated a part, where the spinal marrow is exposed from any bony covering; at which part butchers plunge a pointed knife into what they call the pith of the neck, when they want to kill their animals with freedom and speed, and without the effusion of blood; whence it is called pithing. The remaining five neck bones are not very dissimilar from each other.

6308. The dorsal vertebrae (g) are now and then, though rarely, nineteen in number; they do not differ materially from each other, but in the length of the projection of the spine. The first two or three elongated spines that we observe the height of the withers; and as the intention of these parts seems principally to serve as levers for the muscles of the back inserted into them, so we can readily understand why their increased or diminished height is favourable or unfavourable to progression. These like the foramen magnum is united with each other by the processes, as we have mentioned in other bones; between each of which is interposed a substance, semi-cartilaginous in its structure, which is most compressible at its sides, these permitting the motion of the spine.

6309. The six lumbar vertebrae differ from the foregoing in having a longer body, and very long transverse processes to make up for the deficiency of ribs in the bones. These bones often unite by the pressure of heavy weights, and sometimes spontaneously by age, and thus we need not be surprised at the stiffness with which some old horses rise when down.

6310. The sacral vertebrae (s) are united into one to give strength to the column, and to serve as a fixed support to the pelvis, or basin, with which it is intervertebral. From this detail it will appear how admirably this spinal column is adapted to its important functions of serving as a flexible but powerful support to the machine; and how by the formation of a large foramen within the substance of each vertebra the canal is afforded for the safeguarding of the spinal cord and its branches. The bony openings in these vertebrae, the spinal nerves are given off in pairs. The pelvis or basin (2) is composed of the sternum, the two ossa innominata and coccygis. The ossa innominata in the male calf both bones are each composed of the ilium, the ischium, and the pubis, all traces of which division are lost before birth. The ischium is the most considerable, and forms the haunches by a large unequal protuberance which, when very prominent, occasions the horse to be called raggled-hipped. The next largest portion is the ischium or hip bone, on each side. It forms a part of the cotyloid cavity, or cup for the thigh bone, and then stretches back and inwards, and extends backwards, which form the points of the hip bones. The pubis or shank bone is the least of the three; in conjunction with the former it forms the acetabulum or cup-like cavity in which the head of the thigh-bone lodges. The pelvis or basin is attached to the sacrum by ligaments of immense strength; but it has no bony union, by which means, as in the pore extremities, some play is given, and the jar of bony connection is avoided. The ossa coccygis, or bones of the tail, vary from eight to sixteen, but are very commonly thirteen or fourteen.

6311. The thorax or chest comprises the sternum or breast bone, and the ribs. The sternum (o) of the horse is curved like the keel of a ship, to which the ribs are attached by strong ligaments. The ribs (r) are usually eighteen to each side, of which eight articulate with the sternum, and are called true, while the remaining ten, uniting together by intervening cartilages, are called false ribs. The centrals are the longest, those anterior, as well as posterior, are less so: the first is so prolonged perpendicularly, the second less so; and their obliquity, as well as dimensions, increase as they advance, so as to enlarge the chest to an almost circular form, which is the most desirable; but when they are less arched, the belly parts of the defect, and a flat-squared horse is commonly a bad carcase one also.

6313. An examination of the bony parts of the horse excites our admiration at the wonderful machine displayed in their formation: osseous portions also present themselves, which may be regarded as principally subservient in keeping up that vast chain of continuity and similarity observable throughout Nature's works. In the following explanation we shall have occasion to notice several of these.

6314. The scapula or shoulder blade (b, l), is a broad, flat, and rather triangular bone. It is very unlike the human scapula, having neither acromion, coracoid, nor recurrent process; neither is its situation at all similar to the human blade bone applied to the back; for, in this instance, the horse may be said to
ANATOMY

have no proper back, but to be made up of sides and chest. In man, the scapula is in a direct angle with the humerus, but in the horse it does not pass out of the plane of the arm. Its superior surface is fur-nished with a considerable cartilage, \( i, m \), by means of which its surface is augmented without weight. The humerus, so called glenoid, which receives the head of the arm, or arm bone. It is divided in its upper surface by its spine. The shoulder blade, as has been already shown in the exterior conformation, has neither bony nor ligamentous union, but is held in its situation by the strong ligaments, the conformation of the pectoral, and others. Its principal situation is in a plane perpendicular to the horizon, at an angle of thirty degrees; and it has a motion in its joints of great power and twenty degrees; hence, it does not pass beyond the perpendicular backwards, so the more oblique its natural situation, the more extensive are its motions.

622. The bone called or arm bone is pierced by the musculature by muscles as to be overlooked by a cursory ob-server, and hence the radius or next bone is popularly called the arm. It extends from what is called the point of the shoulder, but which, in fact, is a protuberance of its own to the elbow, forming an angle with the radius and extending obliquely as that does horizontally. Near its upper extremity it sends off a very powerful head to articulate with the shoulder blade. The motions of the humerus are necessarily confined to a removal from its inclined point backward to the perpendicular line of the body. When this bone is too long, it carries the fore leg too much under the animal, and if this defect is joined to a hallowed forefoot, it is a fortunate happening that both the angle and extent of these two parts are usually regulated by each other.

623. The fore-arm \( m, n, o \) is composed of the radius \( oo \), and an appendage united to it, which, in man, is the ulna \( q \), but which, as the horse never requires to rotate much motion, was unnecessary in him. Here, however, to keep the link of resemblance in all her children of the highest order, Nature has stretched out a large process; which in the cot is really distinct, and may then preserve the name of \( i n \); and in the adult horse unites with the radius, and serves as an anchorage for the muscles. On the slightest inspection and the skeleton of the body, it will appear how much the motions of the forearm must depend on the length and breadth of this bone; which, acting on the principle of a lever in the extension of the arm, must necessarily, as it is either long or short, shorten or lengthen the arm. The breadth of the bone is as the lever, as it is called, to the part, will, from this reasoning, be seen to be very important. This bone articulates with the knee by its in-terior portion.

624. The \( m, n, o \), or \( a, b, c \), called the knee or \( d, e, f \), is composed of seven bones, whose principal uses appear to be to sustain the surface of attachment of ligaments and tendons, and by their intertusion to prevent the shocks of progression. It may be remarked that all hooved quadrupeds have the anterior extremities permanently in the state of proration, or with what is called the back of the wrist turned outwards. The horse alone have one investing, or external ligament, which is known as the splint, and which means the smallest wound of the knee which penetrates this ligament has the effect of opening the whole joint; hence the name of syndon or joint oil which escapes in these cases, and hence also the dangerous con-sequences which ensue.

625. The \( m, n, o \) is formed of one large metacarpal bone \( q \), and two small ones \( r \). Here the wide palm of the human, and the paw of the digitated animal, is formed into one solid cylindrical bone, and two small additamentae, called splint bones; which are united with it by strong ligaments, and form ligaments into a bony one. Although the horse has only one of these, the number of bones, as what increase the surface of attachment, their principal use appears to be to keep up the connection with the digit, of which they appear the rudiments. In the cow there are no splint bones, but the uniformity is more nearly kept up by the divided hoof; in her, therefore, the canon branches at its inferior surface into condyles for the reception of the tendons of the paw.

626. The patern \( f \) is the rest of the extremity below the canon, consists of one phalange only, comprising all the mechanism, and a double portion of complexity of all the phalanges of the digitated tribes.

627. The lesser patern or coronary bone \( t, r \) receives the great patern, and below expands into a considerable articulation, and navicular bone.

628. The coffin bone \( w, v \) forms the third phalange, and corresponds in shape with the hoof. It is very porous, and laterally receives two prominent cartilages. It is around the outer surface of this bone that the sensitive lamelae are attached; and the inferior surface receives the flexor tendon.

629. The navicular bone, or shuttle bone, is situated at the posterior part of the collium, and unites with that and the preceding bone.

630. The posterior extremities differ much from the anterior, not only in their superior strength, and in the different lengths and directions of the parts, but also, in some degree, in their uses.

631. The femur, or thigh bone \( 5, 4 \) is the largest of the body, its vast indentations and raisings, almost peculiar to it, show the great strength of the muscles inserted into it. It articulates with the acetabulum or hip joint by a strong head called the whirl-bone. In this situation it is held not only by a powerful capsular ligament, but still more by the strong interosseous ligament, which springs immediately from the middle of its head, and is firmly fixed within the socket of the joint. In its natural situation it is not perpendicular as the human femur, but inclines to an angle of about forty-five degrees. This bone presents large protuberances for the attachment of very powerful muscles. In the horse it differs from the human femur, being shorter, and by its great protuberances of cerility and strength unknown to other animals. The anterior end of this bone is received by its condyles into depressions of the tibia, while the patella, or knee-pan, slides over the anterior portions of both bones.

632. The patella \( 5 \), which is by farriers called the stiffe, is nearly angular, and serves for the insertion of some of the strongest muscles of the thigh, which are then continued down to the leg. It thus appears to act as a pulley.

633. The tibia or leg bone \( 5, 6 \) is usually, in horsemen's language, called the thigh. It is a bone formed of a large epiphysis, with a small attached part called the fibula \( 27 \), a long body, and an irregular interior end, adapted to the peculiarities in shape of the principal bones of the back, with which it articulates. The tibia responds with that attachment, and the long bone, being shorter and more slender as the former is forwards. The length of the tibia is a prominent character in all animals of quick progression; in this respect it corresponds with the fore-arm, and the remarks made on that apply, with even more force to this——that length is advantageous to the creature, but less so to the ease of the motion.

634. The fibula \( 7, 7 \) forms a prominent instance, in common with the splint bones, of what was remarked in the outset of our osteological detail of the extremities——that many parts, whose uses were not apparent, would be found to be organs of harmony, placed in the body to prevent interruption to the completing the general plan of animal organisation. In this way the \( 7, 7 \) appears but a process springing from the posterior part of the tibia, forming but the rudiments of the human bone of that name.
In the ox it is wanting; in the dog and cat, as requiring numerous motions in their limbs, it is, on the contrary, perfect.

88. The tarsus, or hock of the horse (10, 10), is a striking instance of the perfect mechanism displayed in the bony structure of this admired animal. It is formed by an assemblage of six bones, and sometimes of seven; while in the ox, sheep, and deer, there are seldom more than five. Between these bones there is little motion, yet it is sufficiently strong to give a spring to the foot of the animal, and preserve the joints from the effects of shocks. As the human anatomy is generally received as the standard of comparison, we must, in order to a proper consideration of the hock, consider it as the instep and heel; and all the parts beyond it as the foot. The human tarsus, and that of some quadrupeds, is in a right angle; whereas, in the monkey, as before noticed, the point of the heel, and, as in the horse, the head of the great twisted tendons of the gastrocnemius muscles are inserted into it; but the appendage of tendo Achilles would be too forced here. A broad hock, as already observed in the exterior conformation, may be now still more plaited, or even, a tendon, to stay seen to that, the hind leg is fixed to the bone; the lower limb, therefore, must be the lever that the muscles of the thigh act by; and a very slight increase or diminution in its length must make a very great influence in the power of the joint. It is by this tendon acting on this mechanism, that, when the animal has inclined the angle between the foot and the leg, as it does when it stands on one leg, or in the act of taking a leap into the air, it is enabled to open it again. The bones of the hock, like those of the knee, are united together by strong ligamentous fibres; and it is to an inflammation of these uniting the calcaneum and cuboidal bone, that the disease called chibb is to be attributed. The tendo Achillis or the common tendon of the posterior part of the legs, is, altogether, the same in these animals, but is less oblique in its situation; by which wise provision the horse is enabled to elevate and sustain his body entirely on his hinder parts without danger; which would not have been the case if the obliquity of those parts had been considerable.

Subsect. 4. General Functions of the Bony Skeleton.

8580. The skeleton of the horse must be considered as a mechanism of admirable wisdom and contrivance, which having been considered in detail, we offer the following summary of its functions generally as a whole. It will be found to present nearly a quadrilateral figure, having an inclined cylinder resting on four supporting pillars. The spinal column, as the inclined cylinder, serves as a base for the soft parts, and is not truly horizontal, but dipping downwards over the fore legs; by which the propelling force of the hinder extremities is relieved by the maximum of strength thus transferred. The increased weight of the hinder part of the cylinder is admirably counterpoised by the head and neck, which are projected forwards; by these means leaving the line of direction a little to the side of the weight, and not so much to bear the horse upon his own weight. Nature, therefore, has limited the length of the spines of animals: hence, equus equus, a long-backed horse must be weaker than a short one; and thus, likewise, small horses can carry proportionally more than larger ones. The four pillars which support this cylinder are not perpendicular partially; but they are so totally: for a perpendicular drawn from their common centre of gravity will be found to fall nearly in their common base, by which means they are supported as firmly as though their individual axes had been in a line perpendicular to the horizon. Had they been perpendicularly opposed to each other, there could have been but little elastic force, and consequent ease in motion; every exertion would have proved a jar, and every increased effort would have produced luxation or fracture. To increase our admiration of this mechanism, we need only turn our attention to the conformation of these angles in the hind and hinder supporting pillars. Had these angles presented themselves in the same direction, the body must have been precipitated forward; but each offering a counteraction to the other, the body is firmly sustained within them.

8530. The bony masses are operated on by muscles, for this deviation from a perpendicular direction in the various bony portions of the limbs must necessarily have powers to correct it, which is effected by the muscles; and when their power is not so great, the muscles will be found proportionally strong and large. This muscular exertion, to counterbalance the angular inclination, occasions fatigue; as the set of muscles immediately employed becoming weary, the animal is obliged to call another set into action, which change is necessarily more or less momentary in the progress of the animal, and their action, consequently, is not as strong as that, which is weaker. The horse, for this reason is a weaker performer, and his exertions do not move so fast as others with less strength, as the carthorse and racer, or greyhound and mastiff.

8532. The mechanism of the fore and hinder extremities presents some differences. That of the fore limb may be said to exhibit alteration less than that of the latter; for a different character is given to the muscles and tendons in each of the extremities, being fixed purposely to receive the weight imposed upon them by the impulse of the hinder limbs. This weight they are designed to sustain, until the elevation is forced on them by the tendency the general inclined mass has to meet the ground, or to find its common centre of gravity. The fore leg, on the contrary, never has anything similar: and it is only by the impetus communicated by the hind limbs, that the necessary impetus is imparted for the projection of the body forward. This important operation of impelling the mass being almost wholly dependent on the hind extremities, as that of sustaining it is principally confined to the fore extremities; so the former are also much stronger in point of muscular apparatus; by which their angles can be advantageously opened and closed with superior effect in progression.

Sect. IV. Anatomy and Physiology of the Soft Parts.

8533. We shall include under appendages to bone, the muscles and tendons, blood-veossels, arteries, nerves and glands, integuments, head, car, eye, nose, mouth, neck, chest, abdomen, organs of generation, and the foot.

8534. The appendages to bone are cartilages or gristle, periosteum, medulla or marrow, ligaments, and synovia or joint oil.
5635. Cartilages are of three kinds, articular (1887.), which cover the ends of the bones by a thin layer, enabling them to slide on one another; non-articular, or such as are placed between bones immovably joined; unattached, as those of the ears and larynx; and temporary, as the ends of bones in very young animals before their earthy deposit is completed. The general nature of cartilage is smooth, white, very elastic, and hard.

5636. The periosteum is a general uniting membrane to bones and their appendages (1882.); on the skull it is called periconium; when it covers ligaments, periconium; and perichondium, when it invests cartilage. Its use appears to be to furnish vessels to the bones. It is little sensible, except under inflammation, when it becomes highly so.

5637. Melalla, or marrow, is a soft fatty substance deposited in the cavities of bones.

5638. Ligaments (1891.) are close, compact, fibrous substances, of immense strength in the horse, necessary for this purpose, and is a common membrane in every part of the body. Ligament is considered inelastic; there are, however, many exceptions, of the cervical and metacarpal and metatarsal are instances. In some cases they are semicartilaginous. The suspensory ligaments attach and suspend parts, as they do in the horse, to its socket, &c. Capsular ligaments surround the two opposed ends of jointed bones, and form a complete cavity.

5639. The synovia or joint oil, being secreted from the inner surface of the capsular ligaments, fills up this cavity, and affords a slippery film, thickening the bones and enabling the bones to slide readily over each other. In the horse which we term deth, to distinguish it from skin, glistening, bone, ligament, &c. Muscles appear composed of bundles of reddish fibres, the ultimate division of which it is impossible to trace; and as the motions of an animal are various, and as almost all motion is operated through the agency of the muscles, it is evident the muscles of the general shape they take animals possess more than others, particular to those ending in bones, is added a portion of a very different nature, called tendon.

5640. Tendons are insensible, inelastic, tough, fibrous substances, of a whittish colour; expanded into thin layers they are called aponeuroses. The tendons are eminently useful to muscles, diminishing their size without decreasing their strength. What would have become of the light elegant limb, had the mass of muscular masses been continued to their terminations below in equal dimensions? Muscles, when operated on, are very little sensible; whereas the powers of life are very different: one can regenerate itself with ease, the other with extreme difficulty. The muscles also possess a large share of nerves, and consequently of sensibility and irritability, to which properties the surprising phenomena they exhibit must be attributed. They perform their office of vaso-motor with such a skill that any small haemorrhage would prove fatal. The muscular tunic appears to exist in much greater proportion in the horse than in man, and this accounts for his greater tendency to inflammation, and also why inflammatory affections run to their terminations so much sooner in the horse than in man. The arteries gradually decrease in their diameter as they proceed from the heart.

5641. Our knowledge of the terminations of these vessels is very confined; we know they terminate by anastomosis, or by one branch uniting with another. They terminate in veins, and they terminate on secretions surfaces, in cases their contents being changed. Another physiological termination of the arteries is by exhalant openings, by which sweat is produced. The use of the arteries is evidently to convey blood from the heart to different parts of the body, and according to the part the artery proceeds from, or proceeds to, so does it receive an appellation. Perforating blood-vessels are the principal members of this system. Originating from the left ventricle of the heart it soon divides into two branches, one of which, the anterior, or aorta ascendens (fig. 583, p.), proceeds forward to be divided into two principal divisions: the caroticas, &c., by which the heart is supplied by blood, and the caroticas is divided into the external carotida, palpable at the root of the neck, and its branches; the aorta descendens (fig. 583, p.), which is distributed to the trunk and hinder extremities.

5642. The pulmonary artery is a trunk of five or six inches in length; arising out of the anterior ventricle of the heart, and continued by the aorta. It soon divides and enters the lungs, through which it ramifies.

5643. The veins are also membranous canals which begin where the arteries end, and return that blood which has been distributed by them and their appendages. They have less solidity, and possess two tunics or coats only. They usually accompany the arteries in their course, but are more numerous, being wisely divided into a superficial and a deep-seated set, to avoid the dangerous effects of interruption. To prevent the return of the blood they are furnished with valves. The original venal trunk of the horse are ten in number; the anterior cava, the posterior cava, and that to the left pulmonary, by which it may be added the venal portae.

5644. The vena cava passes out of the body by two trunks from separate parts of the right auricle. The anterior cava, or cava ascendens (fig. 583, p.), is opposite to the first rib, divides into four principal trunks; two axillaries, and two jugulars, (fig. 583, p.) The axillaries furnish the fore limbs under the names of the humeral, the ulnar, and the metacarpal arteries. The jugulars (fig. 583, p.) run up one on each side of the neck and thorax to return the blood of the head. The posterior, or cava descendens (fig. 583, p.), returns the blood from the body and hinder extremities.

5645. The vena portae is formed from the veins returning the blood from the viscera, which, uniting to enter a sac of that viscus, are ramified through all parts of the body, and wherever of the live body has not been digested by the alimentary tubes, and enters the heart by the posterior cava.

5646. The blood is a homogeneous fluid, contained in the heart, arteries, and veins, and constantly circulating through the whole body. It appears formed with the body; is read and varied in the veins; is the component parts of the live animal, in the arterial blood; the coagulum; the coagulum, fibrin, or gluten; and the serum. The coagulum is composed of red globules, whose intensity of colour is less in the horse than in man. A red colour is not necessary to the essential proper of the blood; even those things that are furnished with colourless blood, as the transparent part of the eye, &c. The coagulum fibrin or fibrin (1914.) appears to be the most essential part of the blood, and that from which all the parts are formed. The blood forms the dilute the whole. The quantity contained in the body is uncertain; young animals possess more than older, and hence bear bodily injuries better.

It is less in quantity in fat than in lean animals; and in
The nervous system is a very extraordinary and a very important one; for if the blood builds up and repairs parts, the absorbents pull down, remove, and take them away again. They are composed of the lymphatics and lacteals. Both kinds, although thin and transparent, are strong, and appear to have a contractile power: where very minute they are called capillaries. The lacteal absorbents are situated in the mesentery and intestines, whence they draw the chyle from its fluid state and is carried forward from the mesentery into a tube called the thoracic duct, which, passing up by the side of the aorta, pours its contents into the heart through the medium of the jugular vein. The lymphatic absorbents differ from the latter only in being situated over the whole body, and being the receptacles of the various matters of the body: whereas the lacteals appear alone in the horse. From numerous facts, we know that the various organs are continually suffering a destruction and a removal of parts, and that what the absorbents take away, the arteries renew; and to this constant change, most of the alterations of the body are to be attributed with regard to their proper conditions of health. We stimulate the absorbents to take up disced solutions of fluids from various parts of the body, as in watery swellings in the legs by mercury and by friction, or by pressure in the way of bandage. When deposits are made of hard matter, or ligament or bone, we stimulate them by blistering and burning off the integument. Exercise is a very powerful stimulus to absorbents; thus it is that swollen legs are removed by half an hour's exercise. In the horse, the lymphatics are more liable to disease than the lacteals, but in man the reverse. Fancy diseases the lymphatics irreparably.

The cerebral nerves, arising in pairs immediately from the brain, are the olfactory, optic, motorellus, palatini, trigemini, abducens, auditory, lingual, par vagum, and the pair called the internervosus, or sympathetic, from its extensive connection. The testicles are those which arise immediately from the spinal marrow, as the caudals, humerals, uterine, metacarpal, and pectoral nerves; the dorsal, the lumbar, crural, sciatic, popliteal, sartorius, and the nerves to the posterior extremities, which correspond with those of the anterior.

Nerves are numerous, each composed of many fibres, characterised as sensory, composed of all the different vessels enclosed in a membrane; their office appears to be to secrete or form some fluid, as the liver secretes bile, and the kidney urine. They are clasped into foliaceous, globular, glomerulate, and conglomerate; they also receive specific names according to their situations, or according to the fluid they secrete, as lachrymal, salivary, &c.

The cuticle is situated immediately under the hair (1845.), and appears a hard insensible covering, purposely placed to guard or defend the sensible skin underneath. The cuticle lines many of the large orifices of the body; and it is continued into the stomach, lining one half of it. It is perforated by innumerable small vessels that give out and take in various matters; through these blisters act on the true skin, inflame it, and force it to secrete a quantity of fluid, which thus pushes the cuticle from the skin. It exists before birth, and is speedily renewed after birth, when accidentally destroyed, and the skin thickens, with loss of quickness; it contains secretions and secretions in the form of powder, or little scales, over every part of the body, and is that substance called dandruff, which groves are so careful to remove with the currycomb.

The cutaneous is a mucous substance placed like a net between layers of cuticle and skin; and although very universal in animated nature, its use is unknown.

The cölé, cörium, or true skin. (1847.) This very general investment of the body is situated immediately under the two former; it is very vascular, and is furnished with innervations without direct sensibility, and which, without desire, are intended to constitute it as the real organ of touch. It is much thickened by pressure; assuages, from the beatings they are subjected to, have of immense thickness on the rumen. It naturally also exists in various degrees of density according to the wants of the animal. Like the cuticle it is perforated by numerous openings which correspond with those of the latter membrane. Its composition appears principally gelatine, and hence it is employed in the manufacture of glue; its gelatine uniting with the matter called tannin, becomes insoluble.
in water, and then forms leather; and the value of the horse's hide in this particular is sufficiently known.

6362. Adipose membrane and fat. These form very considerable parts of the body of most animals. The adipose membrane is not so universal as the skin; some parts are completely without it, as the eyelids, ears, sheath, and some portions of the extremities. It is cellular, but the cells fortunately do not communicate or the fat would gravitate. The fat is the unctuous juice poured or rather secreted into these cells. It appears in greater quantities in some parts than in others, and in different degrees of consistence; in the belly of some it is hard, and in others; within the bones it is omeagin in all. Different quadrupeds have their fat of different degrees of consistence, from the firm suet of the ox, and the tallow of the sheep, to the soft lard of the hog, and the intermediate state of the horse; it guards the parts, it preserves warmth; but above all, it is a depot against occasional want: thus a fat animal can sustain itself without food much longer than a lean one. The torpid bear comes from his hibernation emancipated, because his constitution has been subsisting on his fat.

6363. Cellular membrane. (1849.) This complete investiture of the body enters every part, and is formed of communicating cells; as we see by the practice of butchers who blow up their meat; and also by the emphysematous effects of a fractured rib, and the gaseous distention in some putrid diseases. It exists in different quantities, and under various modifications of density throughout the body, and is a very universal medium of connection in the form of ligament.

6374. Panniculus carnosus. (1849.) The fleshy pannicle was kindly given to quadrupeds in lieu of hands, to enable them to corrugate or pucker the skin, and thus to shake off dust and insects. It is a thin muscular expansion peculiar to brutes, but not to all, the swine family being denied it. By its attachments it can operate variously, as we see by the uses the horse makes of it. It is very vascular and sensible, also, from the numerous nerves which enter it.

**Subsect. 6. The Head generally.**

6395. The parts of the head are external and internal; some of these have been touched on, as the integuments, &c.: such as have not will follow in the order of their magnitude or situation.

6396. The brain of the horse (fig. 831. a, b, c), contained within the hollow of the skull, is so similar to

831

that of man, that to describe the one is to portray the other. Like the human, it is composed of cerebrum (a), cerebellum (b), and medulla oblongata (c). The medulla spinalis is a direct continuation of the brain in the form of a medullary cord, called the pith or spinal marrow (k), which passes out of the skull through the occipital foramen. The brain appears to be the organ of consciousness, and the nerves which arise out of the medullary cord are the messengers by which sensation and volition are distributed to the various parts of the body.

**Subsect. 7. The Ear.**

6397. The ears of the horse are composed of inner and outer parts. The internal parts do not differ from those of the human, but the outer are adapted to his situation and habits. These exterior parts are composed of the skin, the outer hair, the cartilages, and the muscles by which they are moved. The skin within the ears is furnished with sebaceous glands, which secrete a bitter matter, noxious to insects; and further to guard against these, it is filled with hair; which the false taste of grooms induces them to retire, and thus to expose the animal to dust, hail, rain, and insects.
The form of the ear is dependent on the conchae cartilagine, which is found pointed and small in the 
Atrichonyx, and starshaped, or slightly rounded, in the heavy bodies of the ruminants throughout, which increases its surface, and reflects the sonorous waves. This outer ear is attached to the 
internal, by connecting cartilaginous portions and appropriate ligaments. The parts of the internal 
ear are, the meatus auditorius internus, or passage; the meatus cochleae, or spiral of the cochlea, between the external and internal parts of the tympanum, the eustachian tube, drum, or barrel of the ear; and the 
In the horse, the tympanic membrane is an opening at the anterior and upper angle of the cavity of the tympanum, forming 
a duct which is in part bony, and in part cartilaginous; extending from the tympanum to a large and 
peculiar cavity near the posterior part of the nasal fossa.

The sense of hearing is formed through the medium of the expansion of the soft portion of the 
auditory nerve over the internal ear; sounds, therefore, entering the cavity of the conchae, are reflected 
alternately from its sides into the tympanum, whose oscillations are imparted to the brain.

SUBJECT S. The Eye and its Appendages.

The appendages of the eye are, firstly, a funnel-shaped cavity formed by the confluence of the bones 
of the skull, called the orbit, not placed directly in front as in man, but inclining laterally, to enable the animal 
to enlarge a larger field of view. The eyelids are an upper and under, of which the upper is 
more considerable, and enjoys the greatest motion. United, they form an admirable curtain to defend the 
eye from dust, insects, and the light during sleep; and are moved by two appropriate muscles. Attached 
to the edge of each is a cartilaginous rim, called the tarsus. The cilia, or eyelashes, are not, as in man, 
above and below; the upper lid only is furnished with hairs, and these are not placed in one row, but in 
several smaller rows. The horse has no supercilia or eyebrows, unless we reckon as such the few 
hairs over the orbits. The lacrymal gland is a body lodged within the upper part of the orbit; it is furn 
ished with five or six excretory ducts, which secrete the lacrimal or tears to lubricate the surface of the 
globe. The superciliary tears are carried off by two openings at the inner angle, called panae lac 
rymalia, by which means the tears are at once carried into the nose, and not as in man first into a 
lacrimal sac. The caruncula lacrymalis is a small black substance in view at the inner canthus, whose 
office appears to be that of directing the tears aright in this course. The hair, or nictitating membrane, is an im 
portant part, seen when the eyes are drawn inwards, but which is drawn outwards, and serves the 
function of the conjunctiva, or the coat without the eye; it is the same as the much larger scale in 
the cichlid fish, to which it also becomes visible, which has led ignorant carriages to cut it off, under a suspicion 
that it formed one cause of disease. The use of this nictitating membrane cannot be for a moment 
doubted; it is denied to man and to most quadrupeds, because it is not essential to their protection. The 
dust and dirt from the eyes; but to the horse and most other quadrupeds it is essentially necessary for 
these purposes.

A diagram of the eye (fig. 852) displays the transparent cornea in front of its globe (a), the crystalline lens (b), its posterior convexity (c), its anterior convexity (d), the iris, or curtain (e), the anterior chamber occupied by the aqueous humour of the pupil (g), the posterior chamber filled with the vitreous humour (h), the choroid coat (f), the sclerotic coat (i), and optic nerve (m), rays of light showing the different degrees of refraction they suffer in passing through the humours of the eye (n).

The globe of the eye is composed of coats, chambers, and humours, and is ope 
rated on in its movements by muscles. It may be considered as a smaller cup applied to its margin anteriorly; or as though the segment of a large sphere were adapted to 
that of a smaller one. The substance which gives figure and consistence to the larger segment is the zve 
radial coat (l), which is very firm and fibrous. The anterior chamber (m) is considered, which is transparent, and formed of thin concentric plates of very different degrees of convexity in different animals, and often in similar animals; to a defect in which is ascribed the indistinct vision or 
starts of some horses. The cornea (a) is vascular and sensible, and in an inflamed state it admits 
the red blood, as we see by the interior redness of the eye. The aqueous humour is a fluid of the 
colourless parts of that fluid. Immediately within the sclerotic coat is a thin vascular membrane, called the choroid coat (k), which is spread over it nearly so far as the cornea, where it turns in and expands into the 
libraries processes. It also by a peculiar fold forms a ligament, after which it produces another projection 
into the cavity of the eye, termed the uvula. It is here continuous, and presents a veil perforated 
in the centre.

The pupil of the eye (g) is the perforation which is seen annular in the human, oblong in the 
horse, ox, and sheep, and perpendicular in the cat. The anterior surface of the uvula is covered with a 
membrane, termed iris, on which the colour of the eye depends: in man it is grey, brown, black, or 
blue; in the horse it is usually brown, but now and then white, when the animal is said to be walk 
evocky, but larger and broader than the human brow. The eye in a horse is usually small, and a little 
covered with a black pigment. They are usually attached to the upper margin only, but when any exist 
in the lower they are small; they have been mistaken for disease. The iris (c, f) is capable of accom 
mmodating itself to the circumstances of day or night, so as to admit or shut out the rays of light. It is the 
choroid coat which expands over the central part of the eye. The conjunctiva is a dark mucous substance, called nigrum pigmentum. In animals, whose vision is distinct at night, this 
figure is a lighted colour: in man it is very dark, and its cresural vision is, therefore, inde 
deisible. In the horse is said to be greenish, in the other quadrupeds it is yellowish, but in quadrupeds, lenticular. It is a diseased opacity of this body that forms cataract. The aqueous humour is a limpid fluid which fills up the spaces not occupied by those already described.

The muscles of the eye. The motions of the eyeball are operated by seven muscles; four recti or 
straight, which elevate, degrees, and draw to and from; two oblique, which rotate the eye; and a retract
or chonoid, peculiar to quadrapeds, to draw the eye within the socket and thus preserve it from danger, which draws the globe inwards.

675. The phenomena of vision. If the diagram as examined, it will be evident that the eye of the horse is an opitical instrument of exquisite workmanship and mechanism, admirably adapted to the luminous rays from the various objects around, and to transmit them with truth to the brain. If the luminous rays reflected from objects passed through the eye in a rectilinear course, as they do through the atmosphere, the image of all upon them would be invisible to them, so that all would seem glare and indistinctness; but being refracted or bent by the media through which they pass, the rays finally meet at a point called their focus or focal point. Neither would one simple line of refraction have been sufficient to answer all the purposes of perfect vision, under its various modifications. It is necessary, therefore, that its passages should vary the density of the media of its transit (a n.). In the passage of the rays through the cornea and aqueous humour, they must encounter their first refraction; and it is evident, that the more convex the anterior portion of the eye may be, the more the rays are bent, and the less their refraction; as we may observe, by the horse or horse with this form of eye, should start. The next and largest degree of bending which the eyes receive occurs in their passage through the crystalline lens, which from its leucicar form must necessarily be considerable; in their passage through the vitreous humour a further refraction is effected, till meeting in a perfect medium; the resultant effect of the passage of the object or objects viewed is obtained; the rays forming in their passage numerous cones, the bases of which will be the object viewed, and the apex of each a radiant point. Amidst the number of objects around, it appears that the eye has a capability of collecting rays from them, by the purpose for the superficial rays, and although the general field of view may fall under an angle of vision, yet such rays only as are immediately capable of this convergence produce effect, all others are lost in the black pigment of the eye, apparently placed there purposely to absorb the superfluous rays. As the eye must necessarily have a vast variety of objects pointed out on it whose distances are widely different, there must be some optical adjustment of the powers of the part to enable it to effect a distinct vision of all objects near or remote; but whether this takes place by means of the angle formed on the two opposite axes, or as has been more lately supposed, by the power of itself, is not yet satisfactorily ascertained; certain it is that after the loss of one eye, time is required both in the human and brute subject for the remaining eye to learn to adjust itself to judge of relative distances; which fact is certainly in favour of the opinion that an angle formed by the eye is one of the powers of the organ; and in this we are also aided by the fact, that the very loupe, which have before the loss of an eye been excellent and sure leapers, has afterwards lost the power of measuring their leaps. Were it not for some adjustment of the optical organ itself, the rays reflected from objects very near the eye would fall behind it, and those from distant ones would fall before it; it would be as if the eye were together, the eye of the focus is also assisted in some measure by the iris, which contracts almost to a point when we look at a very minute object; and by this means only permits such rays to pass through as penetrate the centre of the eye: thus such objects will be much more refracted; but when the eye regards distant objects, the iris becomes dilated, and the rays are then viewed through the edges of the lens, and their inclination is thereby lessened.

675. I. The criteria of soundness in the eyes are gained by a careful examination of them; and which experience has shown to be best made by placing the horse within a stable, with his head nearly approachable to the stable door, which should be fully open. Small eyes are found more prone to inflammation than large, and large goggling eyes are more able to accompany a starting horse than lesser ones; and when the conjunctiva is inflamed only in part of the eye, it is not just as if they were affected; at least, animals with such eyes are become affected with the disease popularly called glass eyes, but medically guttae •sfera. It is not, however, to be understood that all starters have defective eyes; many are so from natural timidity, and still more from harsh usage. The eyes should be examined together, not only to observe whether each presents an equal degree of clearness in the transparent part and within the pupil, but also that an equal degree of contraction exists between each of the pupils. This is of much consequence: if any inequality in size or form be observable between the pupils, the least of them has been in some way affected, and will probably become so again. It is even more suspicious when a turbid milkiness appears on any part of the transparent portion; and equally so, when the inferior part looks other than clear; or, in a very strong light, with a lively bluish tinge. When it is at all turbid, viewed under various aspects, regard it attentively, and there may probably be found an inward speck of perfect white; which is the nucleus or central point of an insect that had punctured.

675. A glossy greenish cast in the eye should occasion suspicion, and the hand should be placed over such eye so as to exclude the light; remove the hand suddenly and watch the motions of the iris or cuncto. If the eye begins to dilate, the examination should be continued, and if the eye remains the same, such eyes are totally blind. A blind horse usually carries his ears about, as though in alarm, on his leaving the stable; he also lifts his feet on such occasions, particularly in strange quarters, higher than a sound horse.

SUBSET. 9. The Nose and Sense of Smelling.

675. The organ of smell is, in most quadrupeds, the next in importance to that of vision, and in many points of view is even of more consequence. With the herbivorous tribe, it forms their principal means of judging between the noxious and the innocuous. It is not therefore to be wondered at, that it should in these tribes form so large a portion of the head; nor that it should be so exquisitely gifted with sensibility, or so admirably formed to answer its important purposes. The external parts of the nasal organ are the two nostrils, and as much of their convolutions and linings as come into immediate view. Internally these two cavities are carried upwards into the pharynx, but completely divided by a cartilaginous septum (fig. S31. f). In this course they communicate with numerous openings and cavities, some of which, that enter the nose, are lined by the singular mucous membrane of exquisite vascularity and sensibility; being largely furnished with blood-vessels, which gives them such a tendency to inflame and become red, as we witness under only a slight degree of exertion, and as we see more evident effects on the chest of patients so affected. Here the fibrous ramifications of the olfactory nerves, which are spread over all its surface. It is this membrane which is the peculiar seat of glanders, becoming first inflamed, and next ulcerated throughout its extent; and as the membrane itself appears to be continued to the pharynx and larynx, so we need not wonder why the glanders of the horse, which is at the corium only by simple inflammation, can penetrate this membrane, so readily degenerates into inflammation of the lungs. The common intumescences or coverings of other parts are extended over the nose, but it is little furnished with fat. Of hairs it has a fine covering, which are occasionally removed by the edges of the nostril, within which is a cartilage, the false nostril, as it is termed, formed, whose use appears to be to keep open the canal for the transmission of air, and yet to offer an interruption to extraneous matter. When the nostrils are a little separated, a small canal may be seen, which is the nasal duct leading to the miraculous mucous membrane of the retina, a precious moisture from the eyes. The horse breathes or respirs wholly through his nostrils in all ordinary cases.

680. The sense of smelling. The volatile particles from all odorous bodies are continually passing off from them, and can only some reach the olfactory organ, whose capability of taking cognizance of their qualities appears derived as before pointed out, by the expansion of nervous fibres from the olfactory nerves which transmit impressions to the brain.
The external parts of the mouth are the lips, cheeks, and beard. The lips are made up of flabby musculature, which give them motion every way; they are provided with very fine hairs of skin almost devoid of hair, their exquisite sensibility forms them into an organ of touch; and in this point of view they may be considered as supplying the part of the points of the fingers in man. The cheeks are equally muscular and movable, but are more furnished with hair; and the beard, in addition to this, has hair. Expansion, has a set of long hairs.

The internal parts of the mouth are the teeth already described (630.), the gums, the alveolar edges, the palate, the tongue, and the parts of the great posterior cavity. The gums are a spongy substance which embraces and holds firm the teeth in the orifice which covers the lower part of the channel forms a kind of fold to connect and confine the food.

These folds are called the barbs, and are apt to be mistaken and cut off as excrescences. The bars are the spaces in the jaw left between the grinders and nipple teeth; and which man, ever ready to advance himself from the brute to the human, makes use of the bristle behind them to injure others, and to bear, forced the palate forms a bony arch, covered by membranous folds, which are apt, when the stomach is affected, to become swollen, in which case the horse is said to have the lamпас or lampers. (646.) By means of these ragose folds, the food is retained within the mouth. The curtain of the palate is situated at the hinder part of the cavity, is not interrupted as in man by the pendulous body termed uvula. This palate curtain is intended to shut out the communication between the mouth and the great cavity of the throat. This is, in many cases, when the period of the curtain is forced back and the food passes. From this cause likewise the horse is prevented from breathing but by his nostrils; and when any air does pass by the mouth, as in coughing, cribbiting, &c. it is only effected by a forcible displacement of the curtain.

The tongue is a long, fleshy mass (fig. 831.), which adapts itself below to the form of the channel, and above to the arch of the palate; its external surface is rough by means of papilla, which are inclined backwards, and thus resist the loss of the food received within the mouth. In some animals, as the ox, the tongue is very large, and is cut pointed. The tongue is a very principal organ in mastication, carrying, by its great mobility, the food into every direction until fully acted upon, and finally passing it into the pharynx.

Sense of tasting. It is not observed that this sense is so diversified in brutes as in man; but it is instinctively so correct, that it seldom leads the animal to the herbivorous part of the field; and when it does, there is reason to suspect some present defect in the organ, arising from morbid sympathec, which (as in the instance of salt-water, of which at some times horses will drink immoderately,) prompts them to take in matters they are accustomed to refuse. Taste was given to brutes to regulate their other senses, and thus there are few people of sagacity who are not of opinion that to the tongue, under ordinary circumstances, produces the agreeable effect but such as are proper for food. Nature, therefore, stimulates her creatures to search for edibles by a double motive, the calls of hunger and the pleasures of taste; and these are usually in unison, for the nurse of republic destroys the appetite of taste. (653.)

The pharynx. The cavities of the mouth and nose terminate in the great cavity of the fauces called by this name, to which also is appended another lesser opening called the larvæ, immediately appropriate to the entrance of the trachea or windpipe. Within this great chamber, at the afterpart of the mouth, is situated by a membranous curtain, which is the Eustachian tube opens, and which great membranous hollow is known in man and most quadrupeds (fig. 831.d.) Its use is not understood, but it is probably connected with the voice.

The larýnx is situated at the posterior part of the former cavity, and appears as a cartilaginous box between the os hyoïdes, to which it is attached for support. This cartilaginous box, or entrance to the windpipe, is formed of several pieces, and is furnished with a kind of movable door, which, in ordinary cases, exactly fills up the cavity left by the arch of the palate curtain, thereby shutting the cavity of the mouth, and forcing the animal to breathe through its nasal openings. In extraordinary cases, as when the animal swallows food, this cartilage is forced down, and then it becomes a door to the glottis or funnel part of the trachea, and thus prevents the entrance of extraneous matter into the lungs. All these parts are supplied by numerous muscular cords, a voice.

The voice. The larvæ has also another important office in being the organ of the voice. The cartilages of the larvæ are very movable on one another. They are furnished with muscular cords, which lighten or relax them; besides which, they are also furnished with peculiar and appropriate sacs or cavities, by which the larvæ of brutes and other animals are of greater firmness, and which augment the voices of those animals. The cartilages of the larvæ being acted on by the cordæ vocales, produce different degrees of density, and consequently different degrees of expansion in the larvælæ sacs; by which, either in expiration or inspiration, are produced different degrees of vibration, and consequent intonation. Neigthing say, but by means of the nose, by which the voice is heard. This is proved by slitting the nasal cartilage, which wholly stops it. Knackering, as it is termed, is only a lesser neigh, with shorter, deeper, and less forcible tones. The former sound is used as a call, the latter as a command, which does, with correct modulation, have a significant of joy and affection, and is then beautifully sonorous. The horse has an acute sound produced by inspiration, usually descriptive of lust: in in most other cases his intonations are accompanied by expirations; nor does it appear that the tongue or teeth of the horse are much concerned in the modulations of his voice.

The parotid glands, or, in the language of carriers, the vies, are two considerable bodies on each side of the head, extended from the base of the ear around the angle of the jaw. Each parotid is a conglomerate gland, furrow shell with numerous little ducts, which unite into one, and enter the mouth about the second molar tooth. These glands furnish saliva for the use of the mouth, and it is an indication and gathering, either in them by themselves, or in the maxillary glands, of the quality of the food. Assistant to these in the furnishing of saliva are the maxillary glands, situated within the branches of the lower jaw, and the sublingual also.

The neck. The external parts of the neck are the common coverings which have been described; the cervical ligament, the throat, and the jugular, or neck vein. This is a strong substance, in some parts semimembranous, and in all extremely elastic, stretched from the occipital bone along the back of all the cervical vertebra except the first. Continued on the spinous processes of these vertebra, it fills up the dip or depression of the spinal column of the neck, so completely as to form the neck either into a plane convex or evanescently hollow. A very formidable mass of the head is preserved in its situation, without the necessity of an immense mass of muscle which would, without this contrivance, have been necessary. It is to an injury received at the upper part of this ligament, or neck vein, that the pain in the head is so frequent, and so numerous to allow of particularisation; it is sufficient to say, they most of them run longitudinally. The jugular veins run one on each side of the neck superficially, on the side of the trachea and windpipe, and form the vessel usually bled from (fig. 833. d). A few inches before they reach the angle of the jaw, each divides, forming a branch that goes to the head. The internal parts of the neck are the vortebrae, within which passes the spinal marrow. The carotid arteries pass up under the jugular veins, near the hyoïdes (fig. 833.e). The trachea or wind-
pipe (figs. 833, g), is a large canal for the transmission of air, furnished with rings of membrane and segments of cartilage, rendering it at once flexible and cylindrical hollow. The esóphagus (figs. 831, h & 833) is the continuation of the funnel-like cavity of the pharynx. It is externally muscular, and internally mucous; its function is to allow of the formation of a tract or passage for the act of swallowing. The esóphagus penetrates the chest within the mediastinum, and passing along the spine (fig. 833, l), through an opening in the diaphragm, terminates in the stomach.

Subsect. 12. The Thorax or Chest.

6261. The chest of the horse is bounded anteriorly by the mallei filling up the space between the two first ribs, and posteriorly by the ribs, anteriorly by the vertebral, and below by the sternum or breast bone. In dissecting the horse, after the interior membranes, muscles, &c. are thrown back (fig. 831. b b b), there appear the lobes of the lungs (e e e); the heart (d); mediastinum or membranous division of the chest (e); the sternum or breast-bone (f); the esóphagus (g); and tendinous sheath of the diaphragm, (a d).

6392. When the chest is opened a smooth polished membrane is seen, which covers the surface, and is reflected over its contents; this is called the pleura; and by a junction of the two pleuras, a division of the cavity of the chest is formed, which is called the mediastinum. By this division of the chest into two parts, very important benefits arise; since when one cavity is opened the lungs immediately collapse, but the respiration may be carried on by the other. In a similar manner ulceration may proceed to destroy the lobes of the cavity of the belly itself. But the pleura does not, as in man, appear to take on inflammation independently of the substance of the lungs; thus the horse is not subject to pleurisy.

6394. The thorax, which is a considerable body in the horse, and which forms the sweetbread in calves, is hardly discernible in the old horse. It is situated between the sides of the mediastinum, but its uses are unknown.

6393. The diaphragm or midriff (fig. 831. h, h) is a very important part of the body of the horse, dividing the chest from the belly by its disk, and the lung from the intestines by its continuations. Its fibres radiate from their origins to unite in one tendinous centre (k). In a state of rest it is anteriorly convex, and posteriorly concave; but at each inspiration these appearances are nearly reversed. (6398.) It is perforated for the passage of the vénæ cava, the aorta, the vénæ azygos, thoracic duct, and the inferior vena cava, all which pass through it by means of three openings. It has been found ruptured in some desperate cases of broken wind.

6384. The heart (fig. 831. d) is the great agent of circulation, and is made independent of the will; were it otherwise, man and other animals might cease to live at their own discretion. It first seen surrounding the heart so completely, that it swells within it by means of a little fluid termed pericardium. The heart is a composition of membranous and muscular fibres, having four principal cavities, and several openings. It is situated within the mediastinum, so as to occupy a cavity of its own. The left side of the heart is in a line with the diaphragm, while the right side is directed to the left of the sternum, between the eighth and ninth ribs. Its two ventricles are immediately within its body, and its two auriæ are rather without, appended to it. The left ventricle contains arterial blood, and from it originate all the arteries except the pulmonary. The right ventricle contains the venous blood; it receives all the veins except the pulmonary. Within the ventricle are valves to prevent the return of the blood. The auriæ are less muscular than the ventricles; the left, or pulmonary, opens into the left ventricle; and the right communicates with the right ventricle. Into these, and larger auriæ the anterior and posterior cavae enter by two openings, and into the left, the pulmonary vein pass.

6355. The circulation of the blood may be shortly described as originating with the left ventricle of the heart, which sends its blood, by means of the great vessel called the aorta, to all parts of the chest; and finally returning through the lungs to the right ventricle, which sends its blood, by means of the two cavae, which pour their contents into the right auricle, which immediately forces it into the right ventricle. From the right ventricle it is again forced out into the pulmonary artery, which carries it throughout the lungs to undergo a change, and to be finally returned by eight trunks into the left heart; these immediately empties it into the left ventricle to renew the process described.

636. The lungs are spongy masses divided into right and left, with less divisions called lobes. Their colour varies according to age; thus, in the colt they are of a light lively pink; in the full grown horse they agree to a greyer tint; and in the very old subject, there is of a still deeper tone. The bronchia are continuations of the trachea or windpipe, which, dividing on its entrance into the chest, pass through the substance of the lungs, and are accompanied by ramifications of the pulmonary artery and veins. From the extreme vascularity of these parts they are very liable to inflammation.

637. The theory of inspiration. It is an extraordinary system. The air at birth gasps, and air rushes into the lungs before collapsed; having once felt this stimulus, by a common consent between the diaphragm and intercostal muscles, the cavity of the chest is diminished to expel the air received, and to inspire a fresh quantity; and which process is then continued through life. The body appears vitally nourished by two sources; one by the lungs, which pass forwards in the lungs, circulating throughout their substance, and imbuing, by their contingency or continuity with the air vessels, oxygen gas from the atmospheric air contained in them. In return for the oxygen received, carbon is given out, which passes off in the form of carbonic acid, a gas communicated from the chest to make room for a fresh inhalation, to oxygenate a fresh quantity of blood, and thus to renovate after the vital powers subservient to its influence.

Subsect. 13. The Abdomen.

6386. The viscéra of the abdomen include the stomach (fig. 833. e); lobes of the liver (h); omentum or canal attached to the whole inferior surface of the stomach, (i); spleen (d); the kidneys (e); the bladder, (f); the ovaria (g), the uterus (h); the bladder distended with urine (i); the diaphragm or muscular partition dividing the belly from the chest (k); the esóphagus or gullet proceeding to the stomach (l); trachea (m); vénæ cava ascendens (n); aorta descendens (o), which pass downwards in the vertebral column; the vénæ splanchnicae (p); the splanchnic arteries (q); jugular veins (r); aorta (s); and the maxillary artery, forming the most convenient situation for feeling the pulse (t), which completes the viscéra and general appearances of the horse when laid open.

6387. The abdomen or cavity of the horse is the least cavernous part of the body, and is only an extensive oval cavity containing very important viscéra, which may be considered as the cholecystic, the urinary, and the spermatic, all which are invested by a membrane called the peritonium, which, after covering each of these organs separately, is reflected over the body itself. It is very strong, and is checked as we perceive by the effects of dropy, great tautness, and likewise by the increase in pregnancy. The omentum or canal (c) is the fatty apon which first presents itself on opening an animal's
PRACTICE

part III.

The stomach and its digestive functions. The horse has one stomach only, and that a very small one, drawing a very wide line of separation by this means between his family and the ruminants. In fact the stomach of the horse may be regarded as intermediate between the triturating muscular one of fowls, and the membranous one of the Graminivora. It is peculiarly constructed to keep up this intermediate character, being partly membranous, partly muscular, and partly cuticular; in which latter formation much of its peculiarity consists, with it shares in common with asses, rats, and mice; whose habits of living on grain give them a like claim to this same division. In a state of rest, or only moderately distended, its direction is across the abdomen, and its two orifices directed upwards; but the cardiac or recipient orifice, to which the oesophagus is attached, the most so; while the pyloric or expellent orifice is rather lower, and more inclined backward. The situation of the stomach is immediately contiguous to the diaphragm or great breathing muscle (fig. 833 k k), from which we are at no loss to understand why a very full meal obstructs respiration; and why it is so imprudent to gallop a horse very hard after drinking or eating fully. Small as the stomach is in a natural state, it is yet capable of great distention, as has been witnessed in stomach staggers, when upwards of half a hundred weight of undigested food has been extracted from it. The membranous portion of the stomach is gained from the peritoneum; within this is situated its muscular part, principally composed of longitudinal and transverse layers, by which its motions in digestion are regulated. Around the cardiac orifice of this part, and prevents regurgitation or vomiting in the horse, except under extraordinary circumstances of muscular relaxation and sympathy. It has been already shown that the anterior part of the alimentary canal, as the mouth, throat, and gullet, are lined with cuticle or skin. This cuticle is continued into the stomach, and lines nearly a half of its internal surface, whose office seems to be a membranous decomposition of the food, which the horse has no opportunity of remasticating like the ox, sheep, &c. The villous or sensible portion of the stomach is thrown into folds, so as greatly to increase its surface: here the comminuted food in its passage becomes saturated with the solvent gastric juice, and is then passed forward into the intestines.

680. The derangements of the stomach may be explained from its anatomy. Though small, and its sensible parts still smaller, yet it is subject to more diseases, and more frequent derangement, than is generally supposed. It has been proved to be muscular, and that its digestive functions are performed by means of its muscularity. It has also been shown that the contractile energy of the muscular fibre, is mainly gained from the oxygen derived from the blood; whatever tends to interrupt this separation, as an unhealthy state of the lungs, too quick action of them, &c. must derange the action of the stomach also. The perfection of its digestive powers is also derived from its secreting healthy gastric juice, consequently whatever interrupts this process must likewise interfere with stomachic health; and that such health is more often impaired than is generally supposed, and that many ailments, attributed to other causes, are really dependent on an affection of this organ, experience and observation will readily evince. Out of condition is a most frequent complaint among horsemen; their horses are out of condition, and unfit for work: the appearances are various, but are all well known; yet it is seldom considered that it is owing, in every seven cases out of ten, to the stomach being morbidly affected. (6425) It is evident that too full feeding must derange it, not only by keeping it constantly distended, and thus weakening its capacity; but by entrenching too much on its secreting office, and requiring an inordinate quantity of gastric fluid to saturate an undue quantity of farinaceous matter. The bots, that are frequently found on its cuticular coat, and are there probably harmless, sometimes displace themselves, and settle on the villous part, where they must occasion uneasiness and probable inflammation.

682. The intestines (fig. 831 k, l) in the horse may be considered not merely as secreting organs alone, as in man and many animals, but as really digestive organs, and continuations of the stomachic visera. This is more particularly the case with the small intestines, and may therefore entitle them to the term of alimentary canal, and the large to that of the excremental; the former measure from twenty one to twenty-three yards in length, and the latter from seven and a half to eight yards and a half, according to the size of the animal. The duodenum is the first of the small intestines, commencing at the pyloric orifice of the stomach; the jejunum, which is the next and larger portion, and the ilium (fig. 831 c, c), which is still longer, form the remainder. The alimentary canal in its structure does not differ from the sensible part of the stomach, having like that two plans of muscular fibres, a circular and a longitudinal, by which its peristaltic motions are regulated; the longitudinal shortening the canal, and the circular diminishing its size. The alimentary part of the intestinal canal ends with this small gut, which itself
PHYSIOLOGY OF THE HORSE.

643. The large intestines (fig. 831, k k) in the horse are really deserving of that name, being very capacious; while in man and carnivorous animals they occupy a much smaller portion of the abdomen. They occupy the lower portion of the abdomen; the cecum occupies the right side, and carries its blind end towards the diaphragm, which is not furnished with appendix as in man. Their occurrence is made evident by the following description: the eversion of the extremities of the appendages, and the eversion of the ovaries attributed to the smaller intestines. The colon commences small from the side of the base of the cecum; but soon enlarging, it makes a round turn around the abdomen, when contracting it ends in the rectum, and reaches the posterior portion of the abdomen. They occupy the colon in the way that oxen throw their surfaces into folds, and also form them into a continuation of cells (fig. 831, m n). By these means, the matters are detained to be acted on more fully, and finally they are expelled in dry hardened balls.

644. The digestive process in the horse is one of the most curious as well as one of the most important which goes on in the body. The various actions of an animal body produce relaxation and waste, which are indicated by fatigue and hunger. To restore the one, rest is required, and to restore the other, food becomes necessary. For the herbivorous tribes, vegetable matter is sought for, which being collected, is masticated by the grinders and mixed with saliva, until it becomes a softened mass, when it is passed backwards by the tongue and molar muscles, through the arch of the palate, in the form of a bolus. Received into the pharynx, which rises to receive it, and the action of which forces down the epiglottis, all impediment is removed to its falling in the open funnel of the esophagus; which having received it, the spiral fibres of the esophagus force it inwards into the stomach. While the food remains within the cuticular part, it is acted on by pressure; but being further removed, it meets the action of the gastric fluid, which is reduced to a pulvaceous mass called chyme. In this state it is passed into the intestinal intakes: for in the horse, before observed, the process of digestion is by no means completed in the stomach, as in man and many animals. The exertions of the horse require that he should eat largely and now and then, and have simethaneous with other necessities; for he is not only strong, but his motions are designed to be quick also: it was therefore necessary that some provision should be made by which they should occur to meet these seeming discords. This consists in the mode of digestion, which being partly completed in the stomach, requires a less bulk in that organ, the intestines participating in the labors of digestion, after a longer time or ten pounds of the food. The horse, therefore, takes a moderate portion of food only at a time, which his digestive powers peculiarly fit him to convert into nutrient quickly and efficaciously, by distributing the task through a long tract of canal; instead of confining it, as in man and the Carnivora, to one simple organ, the stomach.

645. The chyme passes into the duodenum from the stomach, where it receives the addition of the biliary and bilary fluids, whose ducts open into that part of the intestinal tracts. Conducted onwards by the creeping peristaltic motion, it passes through this long alimentary tract rather rapidly in the horse; but it is sufficiently long to render it almost inadmissible to the secreting surfaces of the smaller intestines, and probably to have its work of division and absorption begun in it. Arrived at the larger part of the intestinal tract, it is purposely delayed to be fully strained and separated, the open mouths of the lacteals spread over the villous surface receiving the nutritive part under the name of chyle, and the residue being carried backwards as chyle. The chyle orients itself accordingly, is termed lacteals, which pass onwards enveloped in membranous folds termed mesentery, until uniting in a trunk called thoracic duct, their contents are poured into the heart, whereby they become mixed with, and convert into blood, thereby to its quantity being increased and the alterations which are made in the lungs an amelioration of its quality, which it has been shown is equally necessary to the animal.

646. The liver may also be considered as a digestive organ (fig. 833, a b), inasmuch as it secretes a fluid whose office appears to be to quicken the action of the intestines; at the same time that perhaps the very mass of its substance has been already attached to the alimentary viscera. All other animals, except the horse, ass, and deer, are furnished with a receptacle for bile, where it may be retained and rendered more acid: but the horse has no gall bladder, and, in his fetal state, another specialty presents itself in this organ, which is, that he is deprived of a caninus vestibus, and thus the whole of the abdominal blood flows through the liver. From this simplicity of structure in the horse, he is seldom affected with obstructed or concrecte bile; but the organ itself is liable to inflammation, and also to a chronic disease of it through the medium of the stomach.

647. The pancreas is an appendix to digestion also, as we have reason to conclude by its pouring its contents into the duodenum with the bile. It is situated behind the liver, between the stomach and left kidney.

648. The spleen, or silt (fig. 832, d), is a spongy body situated at the greater extremity of the stomach. Its use is likewise not clearly ascertained; but it has been supposed to be that of a reservoir of blood for the stomach.

649. The kidneys are two excretional glands (c c) situated in the lumbar region, the right more forward than the left, and each is a complete organ, formed of an external part, an internal one, and a cavity called the pelvis. From this cavity passes out the duct called the ureter, and brings with it the urine which is secreted within the kidney. The writers convey the urine to the bladder.

650. The urine appears to be a feces of the body, and one from the blood, as it is secreted with the skin in its office. Thus, when the perspiration is great, the urine is less; and on the contrary in winter, when the perspiration is small, the urine is more considerable. The kidneys of the horse are more easily stimulated into increased action by disturbances than those of man or of most other animals; and substances which appear to have a violent action on the urinary organs. Thus new mown hay, kiln-dried oats, etc., will produce diabetes.

651. The bladder of the horse (fig. 833, i) is a membraneous sac for the reception of the urine. It rests on the rectum, and is immediately under the rectum. It is in part peripheral, and communicates with the rectum by a kind of sphincter to prevent the involuntary escape of urine, and at its posterior part it is pierced by the ureters. To the bladder is attached a membraneous pipe called the urethra, which passes through the penis, and by that means ejects the urine.

SUBSEC. 14. The Fetal Calf.

652. The reproductive system is one of the most important of nature's works; and, whether we examine the subject anatomically or physiologically, we shall be convinced that the utmost wisdom and care have
Part III.

PRACTICE OF AGRICULTURE.

The hoof of the horse presents its united parts with great complexity of structure. The whole of the parts of the foot are united by sinews, cartilages, ligaments, and by the tibial and astragalus bones, which are connected by a strong ligament, the ligamentum nuchale. The hoof is divided into two parts, the exterior and interior, the former being the upper part, and the latter the lower part of the foot. The exterior part of the hoof is covered with a horn, the interior with a skin. The horn is composed of a series of scales, which are united by a thin membrane. The skin is a thin layer of connective tissue, which is very elastic, and is covered with a layer of hair, which is shed periodically. The bone of the foot is composed of the tibia, fibula, and tarsal bones, which are united by ligaments. The tendon of the gastrocnemius muscle is attached to the tibia, and that of the soleus muscle is attached to the fibula. The flexor tendons are attached to the tarsal bones, and the extensor tendons are attached to the tarsal bones. The hoof is supported by the tarsal bones, which are united by ligaments. The horse is supplied with blood by the dorsal and saphenous veins, which are fixed in the body. The horse is a quadruped, and is provided with four limbs, which are united by a series of joints. The horse is a ruminant, and is provided with a rumen, a reticulum, and a omasum, which are fixed in the body. The horse is supplied with food by the mouth, which is fixed in the head. The horse is a warm-blooded animal, and is supplied with heat by the circulation of the blood. The horse is a social animal, and is supplied with protection by the herd. The horse is a sensitive animal, and is supplied with senses by the nerves. The horse is a domesticated animal, and is supplied with use by the man. The horse is a useful animal, and is supplied with utility by the services. The horse is a human animal, and is supplied with life by the soul. The horse is a mortal animal, and is supplied with death by the dissolution. The horse is a living animal, and is supplied with being by the soul. The horse is a breathing animal, and is supplied with breath by the lungs.
uncial indentations, to which about five hundred semi-cartilaginous leaves are attached. Each of these is removed by a thread about the line of the forceps. A surgeon who has considered what a vast surface of attachment is formed by these means, the strength of the union will not be wondered at. No common violence can separate these parts, and their use, as so many springs to support the actions of an animal, at once weighty, strong, and extremely agile, must be apparent. The vessels and nerves of the foot are derived from the metacarpal arteries, veins, and nerves, which pass behind the pastern, when the main trunks divide to proceed to each side of the foot, and are ramified from thence throughout. It is a division of the metacarpal nerve on each side of the lesser pastern, or of the larger, as occasion suits, which forms the nerve operation, now in vogue as a remedy for founder.

Sect. V. Diseases of the Horse.

6422. The diseases of the horse are as numerous and as important as his complicated structure, and the artificial state of his present mode of life, would lead one to expect. Until of late the treatment of these diseases was confined to the hands of ignorant farriers, presumptive grooms, or shoeing smiths; and the fate of the animals was commensurate with the wretched treatment they were subjected to. The establishment of official veterinary surgeons, and the effort to disseminate an improved practice, has increased the number of practitioners throughout the country; and we would earnestly recommend an application to one of established reputation in all cases of difficulty and danger. But as it is not always that such a one is within reach, to enable the agriculturist to do in his own hands the means of informing himself, or of being a chirurgical friend, we submit our view of the diseases of the head, neck, trunk, and extremities, preceded by some general observations.

6423. Condition of horses. Being in condition, in stable language, signifies not only perfect health internally, but such an appearance externally as the philosopher would call unattainable, or at least artificial; while the amateur considers it as an essential requisite to the other qualities of the horse. This external condition has at times given a false notion of the horse, a degree of flesh neither being necessary nor emaciation. Even in this sense of the term, condition, must be varied according to the uses of the animal. In the cart horse, provided there be skleeness of coat, looseness of hide, sound wind, freedom from grease or sweated legs, a healthy expression, a fulness and roundness of body, from his bearing or his exertions, will add to the one and assist the other. In the coach horse, the hackney, the hunter, and the racer, a different condition is expected, varying in different degrees from that of the cart horse. In both cart horse and racer, it is equally necessary that the various internal organs should be in a state to act unimpededly for the benefit of the whole animal; but, in addition to this, it is absolutely necessary to the racer, that the greatest possible quantity of animal fibre should be condensed into the smallest possible bulk; and that the absorption of all useless fat and other interstitial matter should be prevented by every possible means, as essentially necessary to unite lightness of body with full strength and elasticity. It is in the attempts to produce such a state in its full perfection, that all the secrets of training consist: but whether a total departure from natural rules, by unnatural heat, deprivation of light, stimulating food, restraint from water, and excessive clothing, are best calculated to promote it, admits of no positive assertion; and it is reasonable to believe, that the dawn of the present century and science, has, by opening the right paths, and throwing light upon the profound darkness which veiled thescience of physical education, has had a tendency to throw light upon the profound darkness which veiled the whole of this science; that the dawn of the present century and science, has, by opening the right paths, and throwing light upon the profound darkness which veiled the whole of this science.

6424. To bring a horse into condition, not only should the purposes he intended for be taken into account, but also his previous state. If he be taken up from grass with much flesh on him, it is evident that what is required is, to remove the soft interstitial matter it may be supposed he has gained by green food, and to replace it by hard flesh; and also to produce a sleekness of coat and beauty of appearance. To accomplish these ends, the horse should be accustomed to clothing and the full heat of the stable by degrees only: and also by degrees only to the medicated change of food, which is best done by mashes. In two or three days a mild dose of physic may be given, during all which moderate exercise only should be done. Within a week or two it may be continued two hours at a time. After the physic has been given, to dress the coat, increase his exercise and his food, and accustom him to an increase of warmth. In four or five days' time again mash him for two days, and give a second dose of physic, a very little stronger than the first. (6444) After this, still further increase his warmth, his exercise, and his food; and if his coat be too soft, and his feet be too large, and his coat will not lay down. A mild dose of physic, or urine balls, &c., are only necessary in the training of hunters, &c., and even in these, a gradual increase of exercise, rather long continued than violent, with proper food, will effect the end, if not so quickly. Many horses are brought into condition, a somewhat different method, to the right one here prescribed, being pursued. If from grass, still mash him for a day or two, by no means stint him in his water, and with his mash let corn be also soaked. If corn be spoiled or malted, it will produce flesh sooner. But even here, give the horse moderate walking exercise, and if he be not too much reduced, a stouter feed of mashes, and grass, aided by good restorative; as medicines give toxic and unpleasant symptoms; but if great emaciation forbid the physic, give him nightly an alterative. (Vet. Pharm. 6590. No. 1.) As his appearance improves, gradually harden his food and increase his exercise.

6425. In the diseased condition of the horse, a general diagnosis has long been already said relates to that alteration from one state to another, neither being an unhealthy one, which custom has rendered necessary; thus a man in training for running or fighting, and a man out of training, are both considered equally healthy. But there are circumstances that produce a morbid state of condition, different from all these. It is common to see horses, which were formerly strong, and of good size, become slender, lame, listless, and emaciated, and have it attributed to some obscure cause. But it is often happens that the stomach has become relaxed and the hide become bound; neither of which readily remove, even though the original evil may be amended. When the relaxed stomach has produced lambs, tramps, and decay, as deglutition, the stomach itself must be attacked. First mash and give a dose of physic; after it has set, commence the treatment, if the horse be of a full habit, by a moderate bleeding and a nightly alterative (Vet. Pharm. 6590. No. 1. or 2.) But if he be not in full, but in low flesh, commence the bleeding daily, (Vet. Pharm. 6590. No. 3.), which will reduce the swelling on the mouth, and loosen the hide. A sudden cold applied to the skin often brings on a want of condition with surfeit. In which cases bleeding, nightly alteratives (Vet. Pharm. 6590. No. 1. or 2.) with or without an assistant dose of physic, as the habit of the horse, the season of the year, and the nature of the case requires, is another mode of treatment for a case of condition, which are to be removed as described. (6478.) Excessive fatigue is also productive of a bad state of condition, which often proves very obstinate. Turning out to very good grass is the quickest cure, and when that is impracticable, soiling in the stall, or ordinating with carrots, turnips, beets root, &c., will be good restoratives; as medicines give toxic and unpleasant symptoms; but if great emaciation forbid the physic, give him nightly an alterative. (Vet. Pharm. 6590. No. 1. or 2.) It will be only necessary to add, that in considering the state of a horse's condition, 3 R
PRACTICE

SUBJECT 2. Inflammatory Diseases of the Horse.

The inflammatory diseases of the horse are numerous, but his fevers are few; a febrile state being brought on by the inflammation of some important organ. Inflammation may be considered as general or diffused, and local or confined, and both seem to arise from an affection of the blood-vessels, and perhaps from a peculiar state of the blood itself.

General or diffuse inflammation constitutes either or extensive inflammatory affection, and appears to consist in an increased action of the heart and arteries, accompanied with an increase of heat. In some instances where the fever is purely symptomatic, and dependent on the inflammation of some important organ, as of the lungs or the intestines, the inflammation appears retarded rather than increased, from the part which you arrive at its passage through the heart.

Local or confined inflammation is also dependent on an affection of the blood-vessels, but confined principally to the blood-vessels of the part affected. It is hatched by redness, heat, hardness, or swelling, heat, or swelling, which in severe inflammation, when in a local part, are brought on by excitement, such as over-feeding, excessive heat, the reaction produced after cold, and the reaction produced by inordinate exertion. These more exterior arise from injuries, the application of improper substances, &c. Inflammations local to one of the very large circulatory system in the horse, his febrile affections rage higher, and terminate sooner, than in man.

The usual termination of inflammatory affections in the horse is, by resolution, effusion, suppuration, and gangrene. Schirrus is not at all a common termination of inflammation in the horse.

There are few diseases more likely to be mistaken by inexperienced farriers than this; it is not to be wondered at, therefore, if indifferent persons should be led into error by it. It appears in two forms, a violent, frantick one, and a sleepy, languishing one; and they appear to be the same as the resulting inflammation of the brain, but on a paralytic affection of the stomach, and whence it is called stomach staggers.

This latter affection, however, may be distinguished from the former by attending to the colour of the eyelids, nose linings, mouth, &c., which, in stomach staggers, are usually a dark red, whereas in the brain, red or yellow.

Inflammation of the brain shows itself, in general cases, by disinclination to food and motion, drowsiness, accompanied by a heaviness and closing of the eyelids, with moisture and redness of them; and also of and the linings of the mouth and nose. Time being the symptom of these synchronous, he sinks to rise no more. In these cases the pulse is apt to be oppressed instead of increased; but most frequently after the first stages he becomes furious, plunges about, and is vicious to himself and others, approaching to a state of madness, in which state he continues till he sinks, or where and his heart rises again, under which state he sinks no more.

The causes of staggers may be various: the immediate are either an original accumulation of blood within the brain, or the translation of the inflammation of some organ to the brain; as a remote cause it is often brought on by walking, without feeding, without using the legs, walking very hard, and at another suffered to remain inactive, but which horses, whether used or not, are equally fed. Suddenly cold, violence, &c., may bring it on.

The treatment of staggers should be begun by abstracting a very large quantity of blood promptly, by leeches, &c., and letting the horse bleed from ten or even twelve quartes, repeating the same until the decurium ceases. After the first bleeding, back rake, throw up a laxative blister [J.et Pharm. 654], blister the head, promote a current of free air in the stable, and treat altogether as directed under other febrile affections.

Looked jaw, stag-cold, or irritable, arises from cold, excessive fatigue, sometimes perhaps from worms, but more often from a wound of some part, as pricks in shoeing, &c. Such wound is seldom in a recent state, but after two or three weeks' continuance, sometimes a year and more is spent, and it is always a flabby unhealthy state of the wound. It is not always produced by an open wound; it is sometimes consequent on a bruise, strain, &c.; and is sometimes brought on by cold, violent exertions, &c. &c. It appears as an affection of the brain, which transmits its morbid irritation to the nervous system, particularly to the nervous system, and may be considered as in a high state of action, giving the horse a peculiar look of energy, as though immediately stepped from full speed, with his nostrils extended, his head raised, and nose carried forward; his legs straddle wide, and his tail is cocked and quivers, as after violent exercise. The jaw is found, if not close, a little adert, yet nearly so, or cold, and very painful.

The treatment is not often successful; but, however, it is sufficiently frequent that it is to, administer the utmost attention. Blame informs us that enormous bleedings have succeeded; but he places his principal dependence on the application of cold by the mouth, or, with an active blister applied the whole length of the spine. Balls of camphor and opium, to the amount of two drachms of each, may be given three hours. If any room remains in the mouth, the ball may be passed up by means of a stick, or it may be given as a drink by means of a syringe; and even while the mouth is entirely closed, he informs us you may give a drink by the nostrils. Moorcroft used also fear, on the contrary, has experienced benefit from a bath, heated to ninety degrees, and kept at that temperature for three hours. White recommends camphor and opium. Wilkinson, of Newmarket, had very successfully, without any violent, by keeping up general, by means of newly stripped sheepskins put on hot. Perhaps if the body were previously rubbed with oil of turpentine one part, and common oil two parts, it might assist Wilkinson's plan. When locked jaw arises from the body, it is proper to use a veterinary surgeon to cut off those arteries which go to the head, but which should be advisable at once to cut off another portion of the tail; which practices, in both instances, would afford a moderate chance of saving the animal. It is necessary further to remark, that it is of great consequence that the bowels be kept free from feces, by taking a considerable quantity of water, and to the regard to the last, they are very important in this disease, as a medicine, that the only one, of giving support. A horse has been kept alive on nourishing clysters alone for seven or eight days. [J.et Pharm. 655.]

Catarhal fever, epidemic catarrh, influenza, distemper, cold, mauluating, &c. These names apply to a common disease, which, often in rainy, variable seasons appears as an epidemic, and affects thousands of horses at once. It is observed to be particularly prevalent in this form in the spring of some years, more than of others. It is not contagious, like the more malignant form, but is brought on by a violent cold, which all the parts of the body, being exposed to a violent cold, of heat with cold, moisture, &c. In crowded cities and large towns it is more prevalent than than in the young than in aged horses. Where it does not exist as an epidemic, it is brought on by an accident, from the disease or injury of the lungs, with which it is very apt to be confounded; and which mistake is often a fatal one, from the treatment being in some essential particulars different. Inflammation of the lungs commences by a short cough, without much other disturbance to the health than the palpation, or the horse to cough; but which is often so considerable as to make him stamp his feet while coughing. If a horse in the distemper coughs early, it is not a hollow, harsh-sounding, and distressing cough of this kind; if he expresses uneasiness, it is principally from a sore throat, which is very common...
DISEASES

In distemper, but by no means common in pneumonia. The sore throat in distemper gives the horse a disposition to refuse his food, or he chews it and lets the quid fall without swallowing it. He refuses water, particularly if it be placed on the ground. His cough is quick, short, and usually sounds more harsh and dry; but though common, this is not invariably the case. His eyes are usually black or blue, and the horse is alternately hot and cold. His nose on looking into it is redder than usual, and sometimes his glands, as well submaxillary or jaw glands, as his parotid or vives, are tumid. On the second or third day excessive weakness comes on; the cough becomes more quick, and the breath which the nose begins to run. After which the horse either runs off the disease by this suppuration, or it goes on to destroy him by the height of the fever, and degree of weakness produced, or by suffocation from water in the chest. Now and then, although recovery takes place, an obstinate cough is left; and in a few cases the disease terminates by the animal being destroyed.

Exercise the horse briskly, then well hand rub him, clothe him warmly, and it is more than probable that the disease will be cut short. But should it proceed, or should the disease have gone on unobserved to the appearance of the symptom detailed, begin by bleeding moderately; when the horse is not improving, remove the fever from the nose. If there have, the bleeding had better be dispensed with, unless the fever appear, from the quick full pulse and redness of the inner surface of the nostrils and cyclidis, to be still so considerable as to require it; in which case we must not be deterred from the policy, if the hectic there be pure and repeated. It will, however, in general cases, be advisable to avoid bleeding after the second day of the attack, or after the discharge has appeared from the nose, or after considerable weakness has come on. In all cases a very cool temperature is essentially requisite: hot stables or hot clothing is very perilous, but particularly the former. A hood is not improper over the head, because it encourages the running to make an early appearance; and for this reason a warm mash may advantageously be hung round the neck three or four times a day. Before the discharge commences, give night and morning the first dose of the medicine, and instead of mash or drink; and if the running has not been as rapid as soon as the weakness has become considerable, give night and morning either of the fever drinks. (Vet. Pharm. 6579. No. 3 or 4.)

Malt washes, when the weakness is great, are proper; at other times bran washes with plenty of chilled water are best. To relieve the suffering, rub the thighs and the side of the horse with cold water, and if the fever has been of long standing, it will be well to cold out in a field each day is proper. Green meat in the stable, when it can be procured, should likewise be given.

463. Malignant epidemic, murrain, or pest. Now and then the distemper or influenza assumes a character of uncommon malignance; which is happily not frequent here, but not unfrequent in continental countries; sweeping off a third of the horse and kine, without any means being found sufficient to arrest its progress. In these cases it is highly contagious, attacking almost all the horses in the country. Dr Layard, and Osmer, English writers of established reputation, noticed the appearances of this disease long ago; and their descriptions are not different from the milder kind noticed (4634), but in degree. The throat is intensely swollen, the eyes are red and head swell, and sometimes these and other parts swell up, and burst. The matter from the nose is bloody, and the stench intolerable; the weakness is also peculiarly great, and shows itself early.

464. The treatment recommended by Blaine is the early use of malt washes; even ale is indispensable. Green meat should be allowed, and must be very cool, is necessary, having a free communication with the open air. As medicine, three doses are necessary, every day, of the malignant epidemic fever drink (Vet. Pharm. 6582); half a pint of yeast with a pint of ale has been given, with good effect, three times a day; also, to prevent the infection from spreading, fumigate the stables and all the outhouses with the preventive fumigation. (Vet. Pharm. 6583.)

SUBSEC. 3. Diseases of the Head.

468. Epilepsy, morgins, studly, or turnstick, are epileptic attacks of greater or less violence, and which are apt to be confounded with the accidental strangulation that sometimes takes place, from a collar too tight, or from driving a horse hard up hill, &c. The epileptic fit may be divided into two classes, one relating to the head, and the other to the body. In the first, the horse is thrown into an indescribable action; he shakes his head, and bares his teeth, and then suddenly falls down, is convulsed, and discharges a few strong yells, is sometimes drenched with sweat, and then sometimes it is very violent, or it may be only a violent shudder. It is often bloody, being found swelled, and almost closed to the light, the veins and arteries are very red, and the eyes and ears of the horse flow down the face perpetually, and the whole head is hot; now and then these appearances come on gradually. The suddenness of the attack makes the complaint to be attributed to accident, as blows, hay-seeds within the eye, &c; and it is frequently difficult to believe that a constitutional attack is the cause of such sudden severe attacks. It is not known what causes these fits; and sometimes both are so attacked in quick succession, some come again clear and well, and remain so an indefinite period, from five or six weeks to many months. Another attack, however, sooner or later follows, which to others succeed, each leaving increased milkiness on the outer coats, and some dismss within the pupil, either from the eyelids, or from the base of the eye, where it sometimes becomes blind, and is afterwards blind totally before the other, it is often the means of preventing the future attack on the remaining one; which has given rise to a custom of putting out one eye to save the other, and which has succeeded. As a constitutional disease, brought on by artificial habits, as excessive exercise and exertion, close unhealthy confinement, the extraction of all these is necessary to remove the complaint, and to prevent a recurrence; but particularly the close, dark, and unventilated state of the stable should be attended to, as well as the removal of the litter, which retains the volatile alkalai of the urine, and the water should be mild and cold, and the horses should be kept dry and warm, but long continued. Under the height of the attack, however, rest is advisable, with moderate light, which may be still further moderated by keeping over the eye or eyes a thick cloth wet with gonial water. (Vet. Pharm. 6575.)

Sometimes one quarter of vinegar, or three to four quarts of water, having been put on the application and whichever is used, the eyes and eyebrows should be kept continually wet with it, which
by exciting evaporation will keep the part cool. A seetom may be introduced under the eye or jaw. In some cases, blistering the forehead or cheek is found useful. The instance before us is of a horse which suffered from a very severe attack of strangles, or inflammation of the back of the throat, which swimming about in the aqueous humour, eventually occasions violent inflammation. The cure consists in letting out the aqueous humour with a lancet, when, if the filaria escaping with the fluid, recovery follows.

4.21. Of evil. This complaint commonly requires the attendance of an experienced practitioner; but the prevention is often in the power of owners, and others about horses: and to this point we shall particularly direct their attention. Evil pole is commonly the effect of accidont. Repeated attempts for the remedial cooper, produce swelling at the nape of the neck, with some tenderness. In this early state, if the collar be removed, and the part be kept continually wet with vinegar and water, the swelling will often disperse; but if, in spite of this, it proceeds to suppuration, let a vent be made for the matter by a seton (625), so that it may readily flow out. Introduce nothing healing, but encourage a free discharge, and it may yet heal atone. When such is not the issue, the disease attacks the ligaments, sinuses form, and the matter burrows under the skin and muscles, when a seton must be introduced from the opening above and should be brought out at the bottom: the seton should be then daily wetted with the liquid blister. (Vet. Pharm. 6702.) Should this plan fail, escharotics will be required in the form of the scaling mixture. (Vet. Pharm. 587.)

4.23. Strangles, rives, or tives. This disease has been likened to the human measles; because it usually attacks every horse, and most of them at a young period, between three and five years. It is fortunate when it attacks colts at grass, as it seldom occasions inconvenience, which has led some persons into error by turning their horses out as soon as attacked; but it is not found that stabled horses suffer any more than those in the open air; and, in a few days, the disease subsides, and the horses recover.

White has conjectured that colts breeding the strangles while at grass are afterwards exempt from glanders, but this wants confirmation. Proser has also affirmed, that inoculation by the matter of strangulated horses, diminishes the disease, and renders the horse not liable to any future attack; but the practice has never gained ground. When the strangles occurs in the stable, and then also in the field, it proves a severe disease, and shows itself under the appearance of a cold, with cough, sore throat, and swelling of the glands under the jaws, or behind and under the ears. Some there is not much external swelling, and the tumouring, and内地 effects a cure; at others they break outwardly, and the disease runs off that way; and sometimes the swellings disperse either by nature or art, which breeders think unfavourable, as they suppose it renders the animal liable to a future attack. This disease has so terrorized their minds, that the cowardly have tried suppository in the manner of their chickens.

4.24. The treatment of strangles. When the swelling lingers, and neither comes forward nor recedes, poultices are preferable to fomentations, which, by leaving the horse wet, promote evaporation and produce cold. Proser recommends blistering the part, as the best mode of promoting supuration. The horse is supposed to have a pair of depoctions, with warm water should be his principal support, unless the complaint last long, and produce much weakness, when mashes should be substituted. Bleeding is only advisable when the early symptoms are violent, as bleeding at the flanks, extreme soreness of throat, with much swelling around it, and considerable cough, in which case bleeding and fever medicines are proper.

4.34. Tives, or tives, is supposed to be a relic of the latter complaint, and it does appear now and then that after the strangles the parotid or wive glands do remain enlarged, which occasionally may be attempted by mercierial frictions; suppuration should be avoided, otherwise the gland may be destroyed.

4.36. Diseases of the mouth, lampas. All horses, but particularly very young ones, are liable to enlargements or ridges of the mouth; dependent not so much on the part itself, but occasioned by an affection of the whole passage of the mouth, throat, and stomach. It is usual to attend to the part only, which is scarified or burnt to little purpose, when a mild dose of physic, or gentle alteratives, would prove more certain expeditives; to which may be added rubbing the ruge themselves with bay or vinegar.

4.37. Briddle sores. When the bit in colt breaking, or in hard-pulling horses, has hurt the bars, care is requisite to prevent the bone becoming carious. Touch daily with syphilam, and cover the bit with leather, unless total rust can be avoided also from causes not apparent. (6547.)

SUBSECT. 4. Diseases of the Neck.

4.49. Frightful withers are brought on usually by pressure from a saddle with too low or narrow a saddletree; and what has been said both with regard to prevention and cure on the subject of pole evil, will extend also to one here also. (6432.)

4.70. Sore throat is common to horses in colds, in influenza, and in strangles. (6434. 6433.) It is discovered by the horse chewing his hay, but instead of swallowing he drops it from his mouth, or, as it is called quids it. He likewise shows a disinclination to drink. In every case, the horse finds it very hard to swallow anything, whether it be dry or liquid, and this is an indication that the throat is severely affected. Water therefore should be held to him, and his hay should be pulled for him: omission of these services greatly aggravates the sufferings of horses labouring under sore throat.

4.71. Patched neck. A very serious swelling sometimes follows on bleeding with a rustty or poisoned lancet, or lacer, and sometimes also from causes not apparent. (6547.)

SUBSECT. 5. The Chest.

4.72. Inflammation of the lungs is a disease to which the horse is peculiarly liable; as we might a priori suspect, from the vast dimensions of his circulatory system, a great alteration from a natural state to which it is most liable. It seems to increase his pulmonary circulation. 4.73. The causes are these deviations remotely, but the immediate attack is generally brought on by sudden cold, acting on a heated surface; and thus it is that knackers and collarmakers in frosty weather generally come down with a disease that dies from this disease with great feeding also. It often commences slowly, a hard dry cough has been slightly noticed, but which has occasioned no alarm for two or three days: gradually however, the cough appears to give the horse pain; he occasionally shivers, and his ears and feet feel colder than the rest of his body; he heaves at the flanks, and the lining of his nose is found to be much more red than usual, in the worst cases it is seen of a purplish hue; the
Inside of the eyelids also are tinged with the inflammation. The appetite now becomes affected; and although there is not much apparent pain, except when the horse coughs, yet there is much anxiety of countenance present. The pulse is usually small but quick. If in this state the horse accidentally or erroneously receives a violent exertion, it is almost certain that his life is at stake, for it happens that this complaint is sometimes mistaken for distemper, and, from a fear of profuse bleeding, the only remedy that is to be depended on is omitted, and the horse is lost. At the veterinary college, in these cases, a small dose of aloes is given every six hours, and after being bled and rowelled, the horse is turned out into the open air to recover from the treatment. Or, the lungs being stable in which a horse is placed in this disease can hardly be too cool; but when entirely turned out, his feet and legs cannot conveniently be hand-rubbed, or bandaged up to promote circulation; neither can we blister a horse when turned out, so conveniently; and on blistering we deplore as the second source of cure.

645. The treatment is to be commenced by attempts at lessening the action of the arterial system by early and large bleedings, as seven or eight quarts from each horse which should be repeated in

moderation. Moderate exercise and soiling in the stable, with mild merciridal physic, form the best

mode of treatment; but frequently the cough resists all these, and terminates in broken wind.

645. A horse, in which case the lungs are not affected, and coughed blood, under the name of coagulated lymph, remains in the trachea or windpipe, and obstructs the free passage of the air; by means of which the roaring noise is made. It is in vain to expect a cure: blistering the throat sometimes slightly relieves it.

646. Cough is a form of pneumonia, and appears dependent on a peculiar irrita-

bility the disease leaves in the bronchial passages, which are found afterwards incapable of bearing any sudden alteration of temperature: thus horses with this kind of cough are excited to it as soon as the stable is heated, or, in fact, by any breath of warm air, the patient exhibiting the situation of the body, or is new to the part. But, besides pneumonia or inflammation of the lungs producing it, it is often brought on likewise by gross feeding, which, weakening the stomach, im-

povertizes the blood, and thus injures the lungs which are fed by that blood. Water also is the same

method in cases in which we expect to see the least benefit by medium feeding on the

green food is often useful, but particularly carrots. The hay should be excellent in quality and small in quantity; and it will be found that soiling in the stable, but particularly a course of

robust, improves the air for turning. It is sometimes advisable, though it is not certain that

treatment. (6478.) Formule of chronic cough balls are seen in the Vet. Pharm. (6960.)

647. Broken wind is also sometimes brought on by pneumonia, and sometimes by occult causes. It is often occasioned by over-exertion after full meals, in which the lungs become permanently affected, persons and persons find some difficulty in detecting broken wind, striking him smartly with a stick at the same time, which often produces the deep sound without the

system; and which is so significant as never to be mistaken when once heard and attended to: but the

principal peculiarity arises from the beating of the flanks, which operate rather by three efforts than by

two as usual. In the first, the air is drawn in, in the usual manner, and the flanks fill up as in common;

in the next, the filling of the flanks is by no means natural; for it is not done by a gradual sinking of the side, but it takes place at once, with a kind of jerk, as though the horse were swallowing; and then a third effort, to turn the muscles of the belly and flanks. It is a circumstance which is frequently observed in

the altered state of the lungs, and has always this effect, whether it be by mixture with the wind, or in any other way should be given but sparingly, for which

they are however very greedy; from which circumstance, as well as that they are peculiarly flatulent, we

learn, that the vitiation of the lungs is either aggravated by the deranged state of the digestive organs;

or that the bowels become weakened by the imperfect action of the lungs. In some few cases a partial rupture of the diaphragm or midriff has been observed in broken wind.

648. Diseases of the belly. Inflamed stomach seldom attacks the horse as an idiopathic affection, but it is not infrequent for the stomach to become inflamed by mineral poisons as well as rendered inert by vegetable ones. Over-distention may also inflame it.

649. Mineral poisons inflame the stomach acutely, and produce excessive distress, and cold sweats; the animal lies down, rolls, gets up again, looks short round to his ribs, stamps with his fore feet, and

pursues an irritable course of perspiration. The mucus distils from the nose and mouth, and the breath is fetid. When copper in the form of vitriolic salts or verdigris has been given, to the foregoing symptoms are usually added inexcusable attempts to vomit. Immediately the poisoning is discovered, four or five quarts of water, followed by a dose of common salts, or the same quantity of water: or when no better substitute is at hand, even strong soap-suds are advisable. Mineral poisons have also another mode of acting, and are often received into the constitution, neither by design to do mischief, but by mistake, and by mistake they are often taken, and by mistake they often have the great surprise of the former instance, but they are equally fatal. A similar treatment with the one already prescribed is necessary; and as soon as the first symptoms are abated, give laxatives, but be always careful not to give too much, as in all these cases, loss of blood should be kept in mind; and though they are also taken away plentifully. As a preventive to this latter mode of poisoning, whenever mineral agents are used, it is prudent every five or six days to stop a while, and then recommence, by which the constitution will part with the poison gradually.

650. Solution is also another mode of poisoning; and though not equally injurious to the stomach, it often proves distressing, and sometimes fatal. Whenever, therefore, mercurials are given, carefully watch the guns, and as soon as they look red, and the horse quails his head, give him a full purge instead of his medicinal.
communicated through the stomach to the nervous system. Dioscorea purpurea or foxglove, Taxus banksiana, and the crescentic water dropwort, Oenanthe inodora or water hemlock, Phellandrium spathulatum or water parsley, Conium maculatum or common hemlock, are all poisonous in a high degree to horses, and may be taken accidentally by the animal as food, or given injudiciously as medicine. Nicotiana or tobacco, and the vegetable acid or vinegar, are also poisonous, and are sometimes used with injudicious effect when intended as remedies. It is little known that a pint of strong vinegar has destroyed a horse. As we cannot remove the matters from the stomach, we must endeavour to adjust their effects on acids by demulcents, as oil, butter, &c: thus, when narcotics have been taken, the mucous salivary may be neutralized by oil of vitriol, and a pint of vinegar, with six of gin, and a quart of ale, may be tried. An excellent domestic remedy might be found in two ounces of flour of mustard mixed with ale or other fluid.

661. Stomach stagners. This peculiar complaint, which has been yet but little understood, appears dependent on the state of the polyphagus, acting on particular foods; and not on what is taken in acting on the stomach, as was supposed by Coleman, White, and others. From later communications of White, he also now appears to consider it as originating in ‘a peculiar state of stomach.’ Blaine always appears ready to acknowledge the existence of inflammation, ‘as a common foundation,’ in every description, and at grass as well as in a stable; and there is reason to think it epidemic, as it is prevalent in some seasons more than in others. It may, perhaps, be regarded now and then as endemic also; under which circumstances it appears confined to certain animals, and to a few wet situations, and where noxious aquatic plants mix themselves with the grasses. When it occurs at grass, the horse is found stupidly dull and asleep with his head resting against something. This has occasioned the disease to be called the sleepy staggers: and it has often been confused with the phrenitis, or inflammation of the brain. (642L.) In the stable the horse dozes, and rests his head in the manger; he then wakes up and falls to eating, which he continues to do until the distention of the stomach becomes enormous; for the peculiarity of the complaint consists in the total stop that is put to digestion, and the uneasy feel of the distension consequent to such indigestion appears to deceive the horse, and by a morbid exertion to force blood to be excreted. In this way he continues eating until the distention prevents the return of the blood from the head, and the animal dies apoplectic, or his stomach bursts with over-distention. More frequently, however, the stomach becomes flabby, inert, and paralytic, and after death presents marks of inflammation towards the pyramids.

665. The treatment. When recovery has taken place, it has occurred only when the disease has been very mild, and has been assisted by stimulating the stomach into action by purgatives, at once active and invigorating, as an ounce of aloes dissolved in half a pint of oil, or a pint of oil might be tried to the amount of 20 or 25 drops in two ounces of tincture of aloes. Warm water in small quantities, or mixed with common salt, should be frequently passed down. Remove every eatable; rake, club, and hand-rub; and, if the determination to the head be extreme, bleed, otherwise avoid it.

666. Inflammation of the bowels, enteritis, or red colic, is a very distinct disease from the gripes, gullion, or fret, with which it is, however, very apt to be confounded to the destruction of many horses. The peritoneal inflammation of the bowels, the one here treated on, is an affection of their outer covering.

667. The causes are various. It is not unfrequently brought on by a sudden translation of cold after great heats, as swimming during hunting, or from the removal of a horse from grass at a time when he has been in a warm and inexact feed, or by drinking of cold water, have brought it on. It begins by restlessness, loss of appetite, and some uneasiness; the mouth is hot and dry; the inner membranes of the mouth, nose, and eyelids are often reduced from natural. As the disease advances, the animal becomes more violent, and is subject to severe attacks of fever, and to rise and fall as frequently as he kicks at his belly, or looks round at his sides, pawing his litter very frequently. The pulse is usually small, quick, or hard; sometimes it is more full and small, but always hard. Breathing is quickened, and the flanks heave; the extremities are alternately hot and cold, but continue longer cold than hot; and the animal is costive: sometimes pain may force a few hardeneds of faces, but the principal contents are retained. Blaine has given the distinguishing textures between this disease and colic, under which head we have stated them.

668. The treatment must be active, and immediate, or much may be expected. Begin by abolishing a considerable quantity of blood, from a large horse to the amount of seven or eight quarts; proceed to back-rub; then take a large whortle of warm gruel. Give by the mouth, if the expense be not considered an object, a pint of castor oil, mixed by means of the yolk of two eggs, with half a pint of broth or weak gruel, or a pint of broth or gruel, or to give olive or horse by a gruel drench, in which six ounces of Epson salts have been dissolved. A sheep skin, immediately as it is removed from the sheep, may be applied to the belly, which should first be well rubbed with the stronger liquid blister. (Fet. Pharm. 632.) The blisters be reapplied in four hours repeated, if the hands be quite clean, and the belly be not taken place, and if the bowels be not unloosed, give more oil, and blister frequently, having first back-raked. Avoid exercise; first hand rub, and afterwards wrap up the extremities to the knees. As a clear passage for the dung is found, the symptoms mitigate, and the animal slowly recovers; but he must be fed at first very sparingly.

669. Inflammation of the inner surface of the intestines, is, in some measure, different from the former, which, as before stated, is an affection of their outer covering; whereas this is usually confined to their villous surface, and may be thought to be occasioned by superabundance of phlegm, or from mineral acids being brought in, particularly mercurials, which often exert more influence on the bowels than on the stomach. It differs from the former in the symptoms being generally accompanied with purging: neither is there usually so much pain or uneasiness present, nor such cold extremities; but the symptoms are precisely the same as from the virulent measles, one horse, or several from three or four quarts is a proper regimen, but can hardly be with propriety continued. The same stimulants to the outside of the belly should be used as in the last disease; but here, warm general clothing is recom- mended, and warm water, the one here, as also hand-washing and the other remedies.

Give astrigent drink (Fet. Pharm. 653). No. I or 2 with a pint of boiled starch every three days, and give the same by club with two quarts of pot liquor, or trip liquor, free from salt.

670. Dysestomiasis. Inflammation of the horse's bowels, is happily not very common, but when met with, is then called by farriars the fistulous secretion from the intestines, for the fat of the body melted down and passing off thus: but dysentery is a peculiar inflammation of the mucous surface of the intestines, not contagious as in the human, nor epidemic, nor expectorated; but the animal is peculiarly costive, and the motions are yet very different from simple diarrhoea, which is a mere increase in the peristaltic motion, by which common aliment are quickly passed through the intestines, and ejected in a liquid form by an increase in their watery secretion. Whereas in the dysentery of the horse, the large quantities of mucous are taken away with the dung surrounding it; but when it does not pass in this way it appears in membranous films like sodden leather, or in stringy evacuations, like morsels of fat floating in water; sometimes there is a little bloody appearance. The usual symptoms of fever are also present, but not in a very high degree.

671. The causes are cold, over-riding, and not unfrequently acid substances within the intestines; change of food has occasioned it, and now and then superpurgation from strong physic.

672. The treatment. In the first stage, bleed considerably, and give, as the first internal remedy, six ounces of castor oil, which will amnify the fecal evacuations considerably; afterwards administer the
DISEASES

but bleeding malt and the 083 warm grains having a pint. If the extraction is performed without written instructions, the medicine flies. Certain which, would if in the stomach and tendinous tissues. If the medicine is then taken on for several hours, it is always proper to bleed to prevent its causing inflammation: bleeding in the mouth is quite useless. Back-rake, and throw up clots of warm water, one after another, as fast as possible. In the intervals of pain, repeated doses of olive oil, of each half a pint; mix and give. White consist of olive oil, of each half a pint and a half; infuse these together, and keep for use. Give a quarter of a pint every hour until full relief is obtained; hand rubbing, wisping, or immersing the bowels with hot water at the time.

Inflammation of the intestines from wounds in the belly frequently occurs; and these injuries may happen in leaping over hedges or pale gates, or may be inflicted by the horns of a cow. Sometimes the wounds are tender, but more frequently the belly is affected, while the skin remains entire; the gut then protrudes and forces out the skin into a tumour. The first thing to be done is to put the gut back, taking care at the same time, otherwise extensive inflammation follows, to remove any dirt or other matter that may be sticking in it; for which purpose, should it be found necessary, it may be washed with warm water, but without the aid of the gut itself, and then the skin only should be stitched up. After that, the skin only should be stitched up, and a cushion of several folds of old linen and tow being placed in the wound, it should be covered by a thick flannel, or any other bandage round the body, and carefully secured. The animal should then be copiously bled, and have its bowels emptied by clamps. The only food he should be allowed is grass, or bran mashes, and that only in a moderate quantity. When the distention of the intestines wholly prevents their retour, it would be prudent to puncture them with a very fine instrument, and thus to suffer the air to escape, which, although subjecting the horse to the risk of inflammation, is better than the certainty of death by haemorrhage, which so frequently prostrates.

Worms of horses are of several kinds. First, bots in the stomach; but which, as they mostly attach themselves to the hard insensible part of that organ, seldom do harm. Clark lancefully supposes they do good, and devises means for furnishing them when not in existence. The bot is the larva of the Gt equus sp., and is found in the stomach of both cattle and horses. It feeds on the grasses, and on a tree in every mention of this part of the horse himself, from whence they pass into the stomach by the food or by being licked off. Certain it is they get there, are hatched, and there remain hanging to the coats of it by two tentacles, receiving their sustenance of all the nourishment of the animal. Of a considerable time they make their way out by the anus, drop on the ground, and are first transformed into round and "after; and give rise to flies. When bot fixt themselves on the sensible portion of the stomach they may do harm; but no medicine that we know of will destroy them. The flies, or large round worm, sometimes occasions mitche, when it exists in great numbers, such as a starting colt, bending of the hide, irregular appetite, and clammy mouth. The best remedy is the Spig-Gro mary-indica or Indian pink, in daily doses of half an ounce. Tar-sita are not common in the horse; now and then they exist, and are best combated by weekly doses of half an ounce. Three ounces. The remedy is to mix up the same of the Brooks, which are the chief, and should it exist, as mucous as at first, again give castor oil, and then follow it by either of the drinks directed for the cure of souring or looseness. (Vet. Pharm. 6552.)

Diarrrhoea or looseness. This complaint originates in an increased peristaltic motion of the intestines. It is caused by the food, and is distended by air, the evacuation being done from the first, and seldom occasioning much fever or disturbance in the general health, unless exceedingly violent. The stools are merely solutions of the aliment, and unmixed with membraneous matter. It sometimes succeeds in complicated cases; at others the food itself enters into new combinations, and forms a purge. Some horses have their bowels constitutionally weak, as lank-sided small-furred ones, where the mechanical pressure promises the contents forwards. Salt mashes and sea water will purge horses violently sometimes. In violent cases, horndown liquors, and throw up the same byเหล (Vet. Pharm. 6552. No. 1). Two days, three times a day; keep the animal warm and quiet. In the milder cases and in habitual souring change the food. The change should be generally from one more moist to one less so, as beans, &c. Bailey will sometimes introduce it. Buck-wheat is often a remedial grain, and increases the diarrrhoea. Efficacious astrigents will be found in the Vet. Pharm. (6552). Repeat either of these night and morning. Give but little water and that little warm.

Colic, flatulently or spasmodically, called also gripes, fret, or gollion, is an important, because a frequent complaint, in which its irritation is converted into a kind of inflammation, either into the red or inflammatory colic, when improperly treated or long continued. It is usually very sudden in its attack.

The causes of colic are not always apparent. It is sometimes occasioned by intestinal stones, which accumulate to a great size, remaining for years in the cells of the colon, until some accidental disturbance occurs an interruption to the peristaltic motion. Cold in its various forms is a parent of colic; but under the form of cold water given when a horse is hot it is most common. In some horses it is so excessive as to become a constitutional disease.

The distinguishing marks between colic and inflammation of the bowels are gained, according to Blaine, by attending to the following circumstances:—In gripes the horse has violent fits of pain, but they run in regular intervals of ease. The pain in red colic is more uniform and lye. Occasionally the pulse is, in general, natural; in red colic it is quicker than natural, and commonly small. The extremities are not usually cold in gripes; in red colic they usually are. In gripes, the horse attempts to roll on his back, which in red colic he seldom does. There are no marks of fever with gripes, as red eye, eyelids, and parched tongue; which, when they are present, have attended some hours. When they have attended some hours, it is always proper to bleed to prevent its ensuing inflammation: bleeding in the mouth is quite useless. Back-rake, and throw up clots of warm water, one after another, as fast as possible. In the intervals of pain, repeated doses of olive oil, of each half a pint; mix and give. White cloth is absorbent, and has the sanction of long experience, it may be tried. An onion is pounded and mixed up with some powdered savin; in default of which, use powdered ginger. This is to be introduced up the rectum as high as possible, and the horse is to be then moved briskly about. An onion put up the funnel is very efficacious. The following is recommended by Blaine:—

Mallagnite, a nostrum; powder opium, one dram; oil of turpentine, three ounces; warm ale, a pint. He also recommends the following more simple remedy as always at hand:—The expressed juice of two or three large onions, common olive oil, of each half a pint; mix and give. White cloth is absorbent, and has the sanction of long experience, it may be tried. An onion is pounded and mixed up with some powdered savin; in default of which, use powdered ginger. This is to be introduced up the rectum as high as possible, and the horse is to be then moved briskly about. An onion put up the funnel is very efficacious. The following is recommended by Blaine:—
less violence. If it be not, however, arrested, the termination will be equally fatal. About the third day the whites of the eyes turn yellow, and the mouth also. Bleeding, blistering, and purgatives form the immediate steps as practised in other cases.

6450. Chronic inflammation or yellow fever. The liver of horses is less complex than that of many other animals, and is therefore not very liable to disease; indeed some authors affirm that the horse is never attacked with it. Yet the skin becomes yellow from the putrescence of the liver, erroneous; and not only does the liver become hardoned and thickened occasionally, but the bile becomes diseased and is thrown out in that state by the blood over the body. If fever be present, bleed, but if the symptoms present no token of active inflammation, give each night ten grains of calomel, and every ten days four grains of alum, and a mild dose of physic. It is also attended with a yellowness of the skin that betokens either an acute or chronic inflammation of the liver. It is the property of every serious inflammation of any of the important organs of the chest and belly, to communiate a portion of the evil to the remote parts of the body, and if they be immediately in conjunction with the liver, thus an affection of the stomach or intestines, of the inflammatory kind, very often occasions redness of the membranes of the nose, eyelids, &c. &c.

6451. Diseases of the urinary organs. Inflammation of the kidneys is an idiopathic affection, not one of frequent occurrence; but as bladder distention, on injuries, such as over-loading, heavy loads, or violent diuretics, it is not unfrequent: when idiopathic, it may be the effect either of cold, heating food, or a transmutation of some other inflammation; in which cases, it comes on suddenly, and assumes the same febrile appearance. A fewcases of the latter intestine inflammations produce what is called a frequent inclination to stated, the quantity made being so small as almost to amount to a stoppage of urine, which is less or more complete, as one or both kidneys are affected. What little urine is made is also at first very thick, and then bloody. When the disease is the effect of external injury, the urine is not so scanty, but is bloody, and the symptom precedes the other. There is usually much pain and stiffness about the loins; and we learn from Blaine, that a swelling and a paralytic affection of the hind leg, of the side of the affected kidney, sometimes is a feature in the complaint. To distinguish this inflammation from that of the neck or body of the bladder, with which it may be confounded, the same author recommends that the hand be passed up the rectum: when, if the affection belong to the kidneys, the bladder, whether full or empty, will not be hotter than usual; but the contrary occurs when any part of the body of the bladder be affected.

6452. The treatment must be active, and in most respects similar to what has been recommended for red colic, as regards empyting the bowels, and endeavouring to lessen the arterial action by bleeding; here we must carefully abstain from irritating the kidneys by diuretics internally, or blisters externally. A little warm sheepskin, or active fomentation of the loins place; and the only sources of counter. Irrigation that are proper; neither should diluting liquors be pressed, on account of the distention they occasion, but no evil can arise from frequent warm clystering.

6453. Chronic inflammation or congestion of the bladder. When the body of the bladder becomes inflamed, there is frequent staling from the very first attack; but when the neck of the bladder, the situation of the bladder, the bladder, whether full or empty, will be hotter than usual; but the contrary occurs when any part of the body of the bladder be affected. It must be evident, that warm, mild, and frequent clystering must here be peculiarly advisable.

6454. Strangury or suppression of urine, incontinence of urine, bloody urine. Strangury may arise from an inflammation to the kidneys, or to the bladder, by strains, or by the absorption of irritating matters. In these cases, bleed if there be fever, and if not, merely evacuating the bladder; a blende of rubbing the hands cold, and warming the water for drink. Bloody urine should be treated in the same way; some horses have such a natural or acquired weakness of kidneys, that to stale their urine on every occasion of over-exercise, the urine is often made from five to six times as much as the custom of it, which are diuretics. Strong diuretics injure horses more than strong physic, and benefit them less than any other of the popular means made use of. In retentions of urine, but particularly in the case of bloody urine, they are absolutely improper. But they are a common term in the farrier’s list, that it seldom if ever occurs; injuries of the kidneys and bladder being usually mistaken for it.

6455. Diabities, profuse staling, or pissing evil. This disease is more frequently on the horse by long-continued diuretics, or from a similar effect brought on by kiln-dried oats, mow-bornay hay, and sonic green vegetables, than acquired from constitutional indisposition. The horse first stales often and profusely, and then becomes weak and debilitated. If his breath is hot, and sweat copious, and his hide is bound from the beginning, and his urine will have a sweet taste; but if his appetite were good, and his coat sleek, bright, and elastic when the urine was first observed to be immaterial, the evil arises from the feeding, exercise, or other management of the horse. Examine into these matters, particularly into the food, and next the water. Examine whether or not the diarrhoeas have been occasioned under an erroneous supposition of increasing the condition, and alter what may be amiss. If this do not remove the complaint, try the following, after Blaine’s directions:—Liver of sulphur, two drachms; sauf alun, three drachms; ool drachms; half an ounce; cetrach; half an ounce; sal, half a drachm: give as a daily drink in a pint of water.

6456. Stone and gravel. Calculous concretions are not uncommon in the large intestines of horses, when they are lodged in the cells usually, and when they occasion but little inconvenience, except a displacement occurs, when serious evils, as colic, inflammation, or total stagnation, follow. In the bladder, stone is very seldom found; and there is reason to believe, that though gravel is a common term in the farrier’s list, that it seldom if ever occurs; injuries of the kidneys and bladder being usually mistaken for it.

Subsect. 6. Diseases of the Skin.

6457. Mange is a contagious disease not uncommon among low-bred and badly kept horses, but which is seldom generated in those properly managed. When it is the effect of impoverished blood, a different course, perhaps better, but useless in burning, but rather than the use of cold, strong, or weak, or heat and cold. If the disease has been occasioned under an erroneous supposition of increasing the condition, and alter what may be amiss. If this do not remove the complaint, try the following, after Blaine’s directions:—Liver of sulphur, two drachms; sea urchin, three drachms; oak drachms; half an ounce; cetrach; half an ounce; sal, half a drachm: give as a daily drink in a pint of water.

6458. Sulfur will now and then degenerate into mange, but more generally it is brought on by a fulness of habit on acted on by sudden transitions from cold to heat, or heat to cold; it is likewise not unfrequently the effect of a deficiency of the composition to the body, which is occasioned on the skin of stiffs. In the early state, bathe them with chamberlyce or instead, and if the disease has been occasioned under an erroneous supposition of increasing the condition, and alter what may be amiss. If this do not remove the complaint, try the following, after Blaine’s directions:—Crudat calamine, two drachms; reserved verum, one ounce; blood, a pounce and a half.

6459. Hide bound is a state of the skin, where the interstitial matter between that and the flabby jari.

689. The marks of glanders are a discharge of purulent matter from ulcerles situated in one or both nostrils, more often from the left than the right. This discharge soon becomes grayish, thick, and white—of egg-like: it afterwards shows bloody streaks, and is fetid. The glands of the jaw of the affected side, called the kernels, swell from an absorption of the virus or poison; and as they exist or do not exist, or as they adhere to the bone or are detached from it, so some prognosis is vainly attempted by farriers, with regard to the disease; for in some few cases these glands are not at all affected, and in a great many they are not only bound down by the affection to the jaw. As there are many diseases which excite a secretion of matter from the nose, it would be difficult to give a considerable Table, and it is not always the case that a disease develops in the nostrils. Sometimes, in such cases a criterion may be drawn from the existence of ulceration within the nose, whenever the disease has become confirmed. These glandular accidents are to be seen in horses kept in buildings with little air, and the preceding nostril; but a solitary chance should not determine the judgment. The health often continues good, and sometimes the condition also, until hectic takes place from absorption, and the lungs participate, when death soon closes the scene.

690. The treatment of glanders, it has already been stated, is so uncertain that it is hardly worth the attempt; however, when the extreme value of the horse or the love of experiment leads to it, it may be regarded as fixed by experience, that nothing but a long course of internal remedies, drawn from the mineral acids, can effect it. The first have all been tried in their endless variety: White recommends the mildest preparations of mercury, as aphisops mineral; under the conviction that the more acute preparations disturb the powers of the constitution so much, as to destroy as effectually as the disease. At the veterinary college the sulphate of copper (bauxite) has been long in use. Others have tried the daily administration of a drink or ball, composed of the following ingredients:—Sulphate of zine, 15 grains; powdered caoutchous, 7 grains; powdered allspice, 15 grains; of the utility of which he gives one or two extraordinary proofs, and Mr. Sewell still attaches much importance to its use, in such daily doses as the horse can bear. But little advantage is to be derived from any medical treatment, but recommends a union of the mineral acids in the same proportions, and with the same cautions, as are detailed under farcy. (690.)

691. The farcy is a disease more easily cured than the glanders, of which our daily experience convinces us; farcy, or farcin, attacks under distinct forms, one of which affects the lymphatics of the skin, and is called the bud or button farcy: the other is primarily confined to the hind legs, which it affects by large indurations, attended with heat and tenderness. A mere dropwise accumulation of water in the legs sometimes occurs, which has no connection whatever with the disease in question. Farcy is very contagious, and is gained from either the matter of farcy or that of glanders.

692. Treatment of farcy. The distended lymphatics or buds may often be traced to one sore, which was the originally inoculated part; and in these cases the destruction of this sore, and that of all the fore-mentioned parts, which is here purely local. But when the disease has proceeded farther, the virus must be destroyed through the medium of the stomach; although, even in these cases, the cure is rendered more speedy and certain, by destroying all the diseased buds, by cautery or by cautery. Farcy is a hard disease, and dividing them by the sharp-knife, when the disease is seated, by cutting each with a lancet, and touching the inner surface with tapis internitalis. The various mineral acids may of them be tried as internal remedies with confidence; never losing sight of the necessity of watching their effects narrowly, and as soon as any derangement of the bowels occurs, treatment should be given in daily doses of fifteen grains; oxide of arsenic may also be given in similar doses. The subacetate of copper (verdigis) may also be tried, often with great advantage, in doses of a drachm daily. Blaine joins these preparations, and strongly recommends the following:—Dynamite of quicksilver, azide of arsenic, subacetate of copper, and eight grains sulphate of copper, one capsule; make into a ball and give every morning, carefully watching the effects; and if it be found to occasion distress, divide, and give half, night and morning. The same author professes to have received great benefit from the use of the following,—A mixture of equal parts of the active juice of saponaria, half of henopetals, and half of the essence of each six ounces, to be given after the ball. It remains to say, that whatever treatment is pursued either with respect to farcy or glanders will be rendered doubly efficacious if green meat be procured, and the horse be fed wholly on it; provided the bowels be kept free, but if the medical tribe, by being joined with green feed, and tender beets, or Beacon meal. When green meat cannot be procured, carrots usually can; and when they cannot, still potatoes may be boiled, or the corn may be scarped or malted. As a proof of the beneficial effects of green meat, a horse, so bad with farcy as to be entirely despaired of, was drawn to the hospital, and although the true disease was not entirely removed, he was enabled to struggle to more; finally, he rose to extend his medical, and perfectly recovered.

693. Shoulder strains are very rare, most of the lamenesses attributed to the shoulder belong to parts, and particularly to the feet. Out of one hundred and twenty cases of lameness in the fore extremities, only four or five laminitis or tarsal laminites are to be met with.

When a shoulder strain does happen, it is commonly the consequence of some slip, by which the arm is forced violently upwards. It is less to be wondered at than at first seems probable, that farriers mistake foot lameness for shoulder strains, when we reflect that a contracted foot occasions inaction, and a distension of the dietibulum, which thus wastes the muscles of the shoulder. Seeing one shoulder smaller than the other, the evil is supposed to be there, and it is pegged, blistered, and fired.
or the horse is swain for its torture, and the increase of the foot's contraction by the confinement. In real shoulder strains, the toe is dragged along the ground while in motion; at rest it is planted forward, but resting on the point of the toe. These are often caused by a blow which has not only extended, but also divided the head, and conse- quently the whole limb unmit, and the foot flat. These differences are highly necessary to attend to, as well as the peculiar difficulty which is always apparent in moving down hill, which he does with reluctance, and by swinging his leg round to avoid flexing it. This lameness may be further brought about by lifting up the fore leg considerably, which, if the evil be in the shoulder, will give great pain. The muscles between the fore legs are likewise tautened and tender in these cases.

6498. The treatment consists, when it is recent, in bleeding in the plate vein, roswelling in the chest, and fomenting with hot water to the loin three times a day. When the bursa is broken, the astrigent wash for straws (Vet. Pharm. 6555. No. 1) for a week; and afterwards, if necessary, proceed to blister in the usual manner.

6499. Strain in the white bone. (6524) This important joint is subject to strain, or its ligaments and muscles, and is often extended, which is more generally a greater force being brought to the foot by the bear, or their powers to resist; a lesion takes place of some of their fibribs, or in lesser injuries their elasticity is injured by being put on the stretch beyond their power of overcoming again. In all such cases, the swelling, and inflammation follows; by astrigent washes.

6500. Treatment. The first indication is the same in this as in all ligamentary strains, which is to moderate the inflammation by fomentations, &c. &c, and when that has subsided, to endeavour by astrigents and braces to restore the tone of the parts: after which, if any swelling remains, from the extravasated blood becomes organized, to promote its absorption by mechanical frictions, and by washing. This applies to all strains, and will direct the treatment therefore of that strain in the articulation of the thigh with the body also.

6501. Strain in the stifled, is treated in the same manner.

6502. Strain or clap in the back sinews. This is generally an injury done to the sheaths of the tendons, or of the ligaments which bind them down. In very aggravat ed cases, it sometimes occurs that even the tendons themselves are extended beyond their capacity. The heat, swelling, and tenderness are first to be brought down by fomentations, and these be extended, the next proceed to poultire with saturnine applications, until the heat and swelling are reduced: then use tonics, astrigent wash (Vet. Pharm. 6555. No. 1 or 2); bandage and exercise very carefully. If swelling remains, and pain and lameness only remains, after all heat is gone, proceed to blister mildly twice. In all cases of ligamentary extension when the heat has subsided, the part may be considered as in a state of atony; and bandages judiciously applied are then proper, particularly during the day.

6503. Joints of the tendons and ligaments of the leg. It is very seldom that the tendons themselves are ruptured, but the suspensory ligaments are more often so, and the evil is called breaking down. It is usually very sudden, and the fistock is brought almost to the ground. A perfect cure is seldom obtained; but the rupture should be immobilized by means already described, and the heels should be raised. A haled stocking or firm bandage, when the inflammation has subsided, is necessary; and firing is often prudent as a permanent bandage.

6504. Strains of the ligaments of the fistock and coffin joints often occur, and may always be distinguished by the heat, tenderness, and swelling. Treat as already described. In all strains of the leg, attended with inflammation, a gourdul poultire is a convenient and useful application. The gourdul water should be mixed with bran; and a warmed stocking being drawn over the foot, and up the leg, it is first tied around the stocking below the breaking bone, and the stocking is then put on, and the stocking and bandage are fired. These are scarify scabiactions, affecting the back of the knee, and ply of the hock; common only in coarse, low-bred, and in cart horses. Wash with soap every day, after which amount with an unguent formed of equal parts of mercurial ointment, tar, and calamine cerate.

6505. Mallenders. The usual cases of broken knees are referrible to wounds in general; and the treat ment of them in nowise differs therefrom, with this caution, that here it is more immediately neces sary, both for appearance and safety, that if any flap of skin hang apart, to cut it off; or the wound will heal with roughened edges. But when the joint of the knee is broken into by the violence of the injury, it becomes of a very different nature, and is known first by the extreme lameness and swelling that occur; and next, by the escape of a slippery mucus not unlike the white of an egg. If this continue to escape, violent inflammation follows, and either the horse or the joint are lost by it. Farriers are apt to attempt to treat these cases of knee dislocation, that of the joint ad, as called, by, one, the bursa is usually not usually followed by the most disastrous consequences. It is, however, necessary to stop the immediate flow, by other means; the best of which is by a fine budding-iron heated. Should the laceration be com pletely cut, it cannot be done; but, for the treatment, bleeding, the low diet, and the other anti-febrile remedies, until the swelling has subsided, when apply the astrigent past recommended by Clark, made of pipe-clay and alum, every day; but by no means introduce any escharotics.

6506. Sulcums and bone spavins. The former are usually situated on the inner side of the cannon or shank before; and as they are situated, so they are more or less injurious. When buried, as it were, within the tendons or back sinews, they are very apt to lame the horse seriously; but when situated on the plain bone, unless they be very large, they seldom do much injury. If a splint be early attended to it is seldom difficult to remove. Blair recommends the swelling to be rubbed night and morning for five or six days, with a drmarch of mercurial ointment, rubbing it well in; after which to apply a blister, and at the end of a fortnight or three weeks to apply another. In very bad cases, he recommends firing in the large form.

6508. Bone spavin is an exostosis of the hock bones, the treatment of which in nowise differs from that of splint; except that as a spavin in general is more injurious than a splint, so it is more necessary to commence the treatment early, and to continue it until the During the treatment, bleeding, the low diet, and the other anti-febrile remedies, until the swelling has subsided, when apply the astrigent paste recommended by Clark, made of pipe-clay and alum, every day; but by no means introduce any escharotics.

6509. Ring bone is of the same nature, being an exostosis or bony circle formed around the coronet, the treatment of which is with the same of that of splint and spavin.

6510. Blood spavin, bog spavin, and thoroughpin, are all of them originally of the nature of windgalls, and are nothing more than enlargements of the bursal capsules described in the anatomy, as surrounding tendons, ligaments, and bones, to furnish them with a lubricating medium. By over-exertion or hard work these bursal bags become extended, and their contents increased and distended into poupy swellings in the hock, called, when on the play, bog spavin. The pressure of this sometimes occasions a varicose state of the vein, which passes through it, and extends in a direction over it, the pressure of which then receives the name of blood spavin. When the bursal enlargement extends through the hock, it is called thoroughpin. When it is situated below, in the bursa of the flexor tendons, near the fisticlock joint, it receives the name of windgall. The treatment of all these cases must be similar in principle, and consists in lessening the dis tended sac; not as was formerly practiced, to the destruction of the hock or pores, but by applying the contents of these windgalls; but by strengthening the sides of the tumes by stimulants or by pressure. The means of the latter are splints and the large iron blister (Vet. Pharm. 6555. No. 1) or astrigent wash. (Vet. Pharm. 6555. No. 1) Bandages assist greatly, when well applied to the part, and in desperate cases firing has been resorted to, which is nothing more than a more violent stimulant, and a more permanent bandage.
DISEASES OF THE HORSE.

6512. Capulet is a bural enlargement of the point of the hock, and is to be treated by friction, astringents, and bandage.

6513. Carb is an inflammation of the ligaments at the back of the hock, and is usually removed by astringents. (Vet. Pharm. 6555.) When it does not give way to these, the sweating liquid blister may be applied. (Vet. Pharm. 6561.)

6514. Cracking and grease may be considered as modifications of one and the same affection, and are commonly brought on by some neglect in all horses; but when they occur in any but the thick-packed low-bred animals, they are invariably so. Over-feeding or under-feeding, but much more frequently the former, will bring it on. A very frequent cause of it is the practice of washing the legs of horses, and suffering them to dry much or almost entirely, with or without evaporation. This will so weaken the legs as to make them rubbed perfectly dry afterwards. When horses have long hairs about their heels, and are washed and then left wet, the evil must be doubled; as the evaporation going on, cools and chills the heels, and this influence will cause these to become more sensitive. Cracks in the heels very often occur in horses removed too suddenly into full keep from previous straw or grass, or from these to a hot stable; which, by the heat and moisture of the litter, occasions a determination of blood and humors to the legs, and they break out into cracks or sores, from which issue a bloody lecherous fluid. Between the sores the hair staves and gets penothered, and the horse finds difficulty and pain in moving.

6515. The treatment must depend on the state in which the animal is at present. If there be reason to suspect that the horse is to be full and foal, let him be in a stable; or wash and give a mild dose of physic. But when some mismanagement is the sole cause, remove that, and if the case be a severe one, by means of an old stocking drawn over the foot, bury the whole heel in a poultice, made of scraped carrots or turnips; which will subdue the irritation, and bring the parts into a state to bear the application of the astringent paste. (Vet. Pharm. 6567.) No. 21. If more convenient, of the astrigent wash. (Vet. Pharm. 6565. No. 1. or 2.) Moderate exercise should be continued, and the heels carefully cleaned from dirt by soft soap and water on each return therefrom; after which, always again apply the astringent.

6516. Grease is nothing more than an aggravated state of the same affection, and is more common to the hind than to the fore legs. Coarse fleshy-legged horses are peculiarly prone to the affection, from the great accumulation that takes place in their legs; and from the difficulty that the carpillaries find in carrying the increased quantity of lymph upwards. In these, long stable confinement should be avoided, and when the horse is used by exercise it should be conducted by frequent and short intervals. Many cart horses never go out but to work: they often work three days incessantly, or nearly so; and they perhaps rest two days entirely. Can it be wondered at, that the change occasions swelling, acting on the blood, and making this so quick, and could it be avoided, by working for an hour, or walking for half an hour night and morning? Stable soiling should be used; bleeding and physicising also in very bad cases; and when the inflammation and irritation or soreness are great, the poultices recommended for cracks should be applied until these circumstances are removed: afterwards commence the use of some of the astringents recommended. (Vet. Pharm. 6555.) White has stated two remarkable cases of grease cut by the application of corrosive sublimate, in the form of a wash, as, by dropping the horse in a tank of water; increasing it to three drachms, if the pain occasioned by the water be not too severe to stand it. These gross horses have been made to great service in bad cases of grease: half a pint of the expressed juice to be given daily as a drink; and a poultice of the herb to be applied to the heels. In some cases of long standing when the running has ceased, a thickened state of the heel remains, which is best removed by firing, and which likewise is a preventive to a return.

6517. Founder of the feet is of two kinds acute and chronic. Acute founder is a disease that, until lately, was less understood than almost any other. After a very severe day's work, or when very much heated, if a horse get a sudden chill by standing in snow or cold water, it is not uncommon for him to be seize with universal stiffness and every symptom of great fever. Such a horse is said to be hotly foun- dered. By degrees, however, it is observed that the animal has an extreme disinclination to remain on its feet; from whence it will appear that the whole of them are affected. When the horse draws his hind legs into the circle, and when he draws his fore feet up, and his hind feet are the seat of the complaint; but which is seldom the case. On feeling the feet they will be found intensely hot, and the pectoral arteries will beat with great violence. After a few days, unless the disease abate, a separation of the hoofs from the coronet takes place, and at last they fall entirely off.

6518. Chronic founder of the disease is far larger in extent, and as dry as the back of the hinder. As was shown in each foot of a gouldard poultice (6565.), give the fever powder or drink. (Vet. Pharm. 6578.) Litter, up to the heels, is to be used, and the blister round them.

6519. Chronic founder, contraction or fever in the feet. The artificial life that horses lead subjects them to many diseases; one of the principal of which is that of contracted feet. Blaine considers a neglect of sufficient paring of hoof, the application of artificial heat from hot stables, and hotter litter, the depriva-

6520. The treatment of contraction in the feet. It is better to prevent, than to be under the necessity of aiming at cure, the evil. Prevention may be practiced by avoiding the acting causes. As soon as at all suspected to be likely to occur, keep the hoofs pared low; never suffer the horse to stand on litter, nor allow a foot to stand on hard and never allow him to go bare-backed, or to be swaged, on what ever increases the general fullness of habit, flies to the feet. Above all, keep the feet moist by means of wet cloths tied loosely round the coronet, falling over the whole hoof, but not extending beyond the edge. Then moisten repeatedly, and stop the feet (6575.) every night. When contracting the feet, naturally take care not to let them freeze, as jointed shoes, or collar shoes, or Clark's, and others; but it is not found that mechanical expansion in this way produces permanent benefit. The most effectual mode is to obviate all previous causes of contraction; and then to thin the hoofs around the heels from each quadrant, and a poultice of a weak decoction of the drugs used for the purpose of expanding the horn as is consistent with safety, from the coronet downwards. It is also prudent to put in a score or two above from downwards, drawn a quarter of an inch deep on each side towards the front of the hoof; but whether this be done or not, the front of the hoof should be rasped thin about an inch below the point, by which means you will most advantageously temper the hoofs. After this is done, tips should be put on, and the horse should be turned out to grass, where he should remain three months, by which time the new formed hoofs will have reached the ground, and will bear a score. This process is illustrated by the "Exterior Outlines," which the plate completely elucidates the operation, and to which the reader may be referred.

6521. The premoued foot is a very common consequence of acute founder, in which the elasticity of the laminae becoming destroyed, the support of the colli bone is removed, and it rests wholly on the sole,
which it gradually sinks from a concave to a convex surface, drawing with it the front of the hoof inwards. In weak, broad, heavy feet, this evil comes on sometimes without founder; the treatment can be only palliative, a wide-webbed shoe exactly fitted to the foot, without at all pressing on it, prevents the lame-ness, or at least the danger of the disease. A shoe exactly the contrary to this has been tried in some cases with benefit, the form of which has been described, so narrow, and lightly made, with a vane, that it appears to be the same as to remove the feet from accidental pressure. In other cases, no shoe answers so well as a strong bar shoe. (660.)

653. The treatment of corns is seldom difficult or unsuccessful at their first appearance, but afterwards it can be only palliative. Blaine directs that, by means of a fine drawing-knife, every portion of diseased horn should be pared away, and the extravasation underneath lixiviated. Having done this, he advises to introduce some butter of antimony into the opening, to place over this some tow, which should be kept in its place by means of a splint. If any contraction of the heels (fig. 855. a a) be present, it will materially assist the cure to lower them, and to thin the hoof a little around the quarters, and afterwards to put on a shoe without heels opposed to the corn, or a shoe chambered opposite the weak part; or a bar shoe may be applied, so framed as completely to leave the heel untouched. Introduce the butter of antimony once or twice more, with the interval of two days between, and then turn the horse out to grass: in about six weeks' time the corn will be seen. The treatment of corns thus differ; for although they are never wholly eradicated, they may be rendered but little troublesome. The diseased part must be carefully pared out at each shoeing, and such a shoe put on as will completely free the foot from pressure.

654. Running thrush is always a dangerous disease, and few errors in horse management are more glaring than the common one of supposing they are necessary to carry off humour. If less food, more exercise, cool stables, and dry standings, were substituted for the correction, instead of thrushes, which attest the fault, they continued or returned, they would be saved to the community. To the cure, begin by clearing out all the fissures of the frog (fig. 835. a a) from horse ragged horn, and then introduce to the bottom of the sinuses, by means of a thin piece of the dressing of the thrush prescribed. 6554.1. from Ac. Phs. vulg. of the dressing placed between the heel within the eft, especially if it be guarded by splints of wood passed under the shoe; renew the dressing daily; turning out to grass may be practised to great advantage for thrushes by this mode of dressing; but without it the disease is sometimes aggravated.

656. Syphilis of the cornea, figures in a horse before, and usually towards the inner, but now and then towards the outer quarter also, from above downwards: from the crack, a little oozing of blood or moisture is seen; and the sensible parts underneath getting between the edges of horn, become prominent, and the horse crossesways, is easily excited, and his whole four feet are affected: the divided and the undivided parts of the hoof. With melted pitch close up the origin if the oozing be moderate, and bandage tightly. Watch the foot, and if inflammation succeeds this plan, remove the dressing.

657. Pricks or punctures in the feet are often very serious evils, either when received by nails in shoeing, or by one picked up on the road, &c. The danger arises from the inflammation, which is always great from any injury done to the sensible and vascular parts within the foot. This inflammation quickly proceeds to suppuration; and the matter is apt to make its way upwards, unless it find a ready vent below. When it does not break out at the coronet, it will often penetrate under the sole, and finally disease the bones, ligaments, or cartilages, and produce quitter. It is very seldom that a horse is pricked in shoeing, but that the sun is aware of it by the peculiarity of the feet on the hammer, and by the flinching of the animal. When this last occurs, the worst is to be feared, end it is essential to remove the crust which prevents some spirit within the puncture, nothing would occur; but on the contrary, he sends the horse home to avoid trouble, who, next the following day, is found lame, and with his foot hot. If the nail be only stuck, and the sensible lameness disappears, it will only result in a slight evil; but if it have been driven through, and have wounded them, then suppuration ensues, and on examining the foot by the pinners when the shoe is removed, he will find at the pressure on the diseased part, if it is not readily, on the removal of the shoe, that matter will at once flow out at the immediate nail hole. If not, the injured nail will soon detect the injury. If the heat be great, and instead of matter bloody dark ichor flows out, wrap the foot up in a poultice; but if healthy matter flows out, this will not be necessary sometimes it is requisite to detach all the horn that is underrun by the matter; but when the injury has not proceeded to this extent, apply over the part a plad of tow steeped in frar's balsam; tack on the shoe lightly, and retain the dressing by means of splints, which are thin pieces of wood (the withy which binds birk brooms is convenient for the purpose) passed under the shoe; repeat the dressing daily, as the matter moistures, which may encourage quitter. A nail picked up on the road, and which passes through the sole, below or through the frog, is to be treated the same, but if it be of the same material breaks out at the coronet; but when a nail is picked up, and penetrates the collin joint, which is known by the synovia or joint oil appearing, such opening should be immediately stopped by paring towards the joint, and the desicated wound covered over with a coating of healing dressing, and the box bandaged, but so to the skin immediately near it; if this be inconvenient, put a pledget dipped in a little butter of antimony just within the opening, but do not press into it the cavity of the joint: if this be insufficient to stop the flux, put more particular dressings, and the original wound penetrated to the bone, it is probable that the bone itself will become, in some measure, diseased, which it is to be feared may be the cause of the probing when passed. In this case, enlarge the opening so as to be able to scrape the diseased bone away. Bruises of the sole, from whatever cause, will all fall under some of these points of view, according as the necessity may be.

658. Quitter and canker are the consequences of these injures when neglected, or originally extensive. In these cases either the bones, ligaments, or cartilages, or all, become diseased; and a cure can only be obtained by the diseased bone, or in some cases by the knife. They are often occasioned by the knife or by over-reaching. (660.)

659. Treads, over-reaching, &c. A wound on the coronet is not uncommon from one foot being placed on the other, and the hinder foot may strike it, &c. First wipe away the dirt, and remove any loose edges that cannot unite; avoid washing, unless stones and dirt are suspected to be within, and bind up, having first washed and then wound a poultice of lime or benzoine paste, mixed of salt, myrrh, or of aloes, &c. Over-reaching, or over-stepping, is often an injury done to the fetlock joint by, the hinder foot, or to the back shew higher up. Sometimes it is simply a violent bruise, at others the laceration is extensive, in which cases treat as a tred, and when no laceration has taken place treat as a bruise or strain.

660. Cutting is a defect to which some horses are liable from their form, as when they turn their toes
out, or have bent legs. Others cut only when they are lean, which brings their legs nearer together. Weak horses cut because they cross their legs when fatigued, and young unfurnished horses cut at youthful period,-and grow out of it afterwards. The part in which a foot interferes with the opposed limb is very different. When it is high up it is called a high cut, and is best remedied by wearing knee-boots or rollers. When it is at the fetlock the cutting is at the side, or rather backward, according to circumstances. Some horses cut by the edge of the shoe, others by the hoof at the quarters; and some by the point of the heel. It may be remarked, that it is better to put up with the evil of cutting, than to do as is too frequently done, which is, to pare away the hoof until it excruciates. The shoe may be feather edged, or it may be set a little within the cutting quarter; but by no means alter the size or the form of the hoofs themselves, and particularly avoid taking liberties of this kind with the frog. It is no more trouble to get rid of a horn, and when not buckled too tight, it will never injure: whereas, to allow a horse to continue to cut produces a callus, and often throws the animal down.

Sect. VI. Veterinary Operations.

6530. The general practices to be here enumerated are chiefly the treatment of wounds, the application of fomentations, setons, blisters, clays, and physiciggs; and the operations of cauterising, nicking, bleeding, &c.

Subsect. 1. Treatment of Wounds.

6531. A wound must be treated, in some measure, according to the part of the horse's body in which it happens; but there are some principles to be observed alike in all horse surgery. There are like-wise a few, which, as they differ from those of human surgery, should be first noticed, and which should guide the practice of those who might be misled by analogy. The wounds of horses, however carefully brought together and confined in their situation, as well as shut out from the stimulus of the external air, are seldom disposed to unite at once, or as it is called in surgical language, by the first intention. As the adhesive inflammation does now and then occur, we should never wash a mere laceration with water or other liquids, if no foreign matter, or other suspicion be supposed to be lodged within it, still less should we attempt to cauterise with some volatile liquid to speed up the healing of any kind. On the contrary, we should consider the wound as carefully as if it had never been brought together, and simply bound up in its own blood; and if it do not wholly unite at once, and by the first intention, perhaps some portion of it may; and, at all events, its future progress will be more natural, especially if attended with tents, to prevent the introduction of air, or irritants of any kind. When an extensively lacerated wound takes place, it is common, and it is often necessary to insert sutures, or stitches, into the lips of the wound: and here we have to notice another considerable variation from the principles of human inflammation, which is, that these stitches in the horse, ox, and dog, soon ulcerate out, seldom remaining longer than the third or fourth day at farthest. It therefore is the more necessary to be careful, that by perfect rest, and the appropriation of good bandages, we secure the wound from distortion. In this we may be assisted by strips of sticking plaster, made with diachylon and pitch; but these strips should be removed from touching the wound itself, lest the infection be introduced from them. The dressing must be changed, and a similar one repeated, at least every three days, and if necessary, every day. When, in addition to laceration in a wound, there is a destruction of substance, then the caution of washing will not apply, as it will be necessary to bathe with some warming spirit, as tincture of myrrh, that will have the effect of restoring the life of the part, and also of preventing mortification. Bleeding must be stopped by pressure and astringents, as powdered alum: when it is very considerable, the vessel from whence the blood comes must be taken up. When great inflammation follows wounds or bruises, counteract it by bleeding, a cooling temperature, opening medicines, and continual fomentations to the part itself.

Subsect. 2. Baths and Drinks.

6532. Mode of giving a ball. Back the horse in his stall, and being elevated on a stool (not a bucket turned upside down), gently draw the tongue a little out of the mouth, so as to prevent its rising to reach the back of the hand; hold the ball in the hand, and the hand should be held firmly by the fingers of the left hand against the jaw. The ball previously oiled, being taken into the right hand, which should be squeezed into as narrow a shape as possible, must be passed up close to the roof of the mouth, and the ball placed on the roof of the tongue, when both hands being with drawn, it will readily pass down. This method is much preferable, when a person is at hand, to using a balling iron. At Long's, a veterinary surgeon's instrument maker, is sold a clever machine for this purpose.

6533. Mode of giving a drink. Exactly the same process is pursued, except that a horn holding the liquid matter is forced up the mouth; the passage being raised beyond the level line, the liquid is poured out from the larger end of the horn, and when the tongue is loosened it is swallowed. Clark, however, ingeniously proposes to substitute the smaller end of the horn, the larger being closed, by which, he says, the water is forced up the mouth between the teeth, and poured farther back so as to ensure its not returning.

Subsect. 3. Fomentations and Poultices.

6534. Fomentations are very commonly recommended of various herbs, as rue, chamomile, St. John's wort, and marigold, which outward virtue is to be expected in warm applications, which can be obtained by unloading the vessels: but this warmth ought not to be too considerable, except when the inflammation is within, as in inflamed bowels. Here we foment to stimulate the skin, and cannot foment too hot: but when we do it at once to an inflamed part, it ought not to be more than of blood heat; and it should be continued long, and a small portion should be taken. When the part should be dried or covered, or cold may be taken, and the inflammation increased instead of diminished. Anodyne fomentations are made of poppy heads, and of tobacco, and are frequently of great use.

6535. Method of applying Fomentations. This operation is conveniently done by means of two large woolen cloths wrung out of the heated liquors, as one is cooling the other should be ready to be applied.

6536. Poultices act in the same way as fomentations in allaying irritation and inflammation; but are in some respects more convenient, because they act continually. It is an error to suppose that poultices, to be therapeutically efficient, should be very hot; however hot they may be applied, they soon become of the temperature of the surrounding parts. When poultices are applied to the extremities, a stocking, as has been before stated, is a convenient method of application. When it is drawn over the leg and bound around the lower part of the hoof, or of the paw, or, on the other hand, this is not applied within, and it may be then kept in its situation, if high up on the extremity, by means of tape fastened to one part of it, and passed over the withers or back to the other side, and again fastened to the stocking. In this way, also, loose bandages may be retained from slipping down. Cold poultices or ice, in the inflammations arising from strains, &c. In these cases bran and cold water form a convenient medium; but when the poultice is necessarily hot, a little linseed meal added to the bran will render it adhesive, and give it consistence. It is a very necessary caution in this, as in every instance where bandages are wound around the extremities, to have them broad, and only so tight as to secure the matters contained, as in a poultice, or as in common bandaging.

537. Clysters are often useful in keeping up a drain to draw what are termed humours from parts; or by the other part, they lessen in the inflammation in the eye, and in the cheek for ophthalmia or inflamed eyes. They also in the same way lessen old swellings by exciting absorption. Another useful action they have is to make a dependent or convenient orifice for the escape of lodged matter; thus a clyster passed from the upper part of the opening of pale evil, through the upper part of the bladder, will easily cause the matter to pass out of the neck, opening a passage for further application. The same with fistulous withers, which sometimes run under the shoulder blade, and appear at the arm point; in which cases a blunt clyster, needle of sufficient length to be passed down to that point, and to be thence drawn out, will form the only efficient mode of treatment. Clysters may be passed in domestic farriery with a common packing needle and a skien of thread, or piece of tape; but in professional farriery they are made by a proper needle armed with tape or lamp cotton, or skiens of thread or silk smeared over with digestive ointment. When the clyster needle is removed, the ends of the tape should be cut shorter, or otherwise removed, to prevent the formation of loops.

538. Rowels in their intention act as clysters, and as irrigating a larger surface, so when a general drain is required they act better; as in pro tease, &c., but when their action is confined to a part only, clysters are more convenient. In this way many persons are cured by making a rowel in about an inch, cutting with the finger along the sides, and inserting in the opening a piece of round leather with a hole in the middle smeared with a blistering ointment. Then plug the opening with tow; and in three days, when the suppuration has begun, remove it. The rowel leather is afterwards to be daily moved and cleaned.

SUBSECT. 5. Blistering and Firing.

539. Blistering answers the same purpose as clysters; and is practised by first cutting or shaving the hair from the part, when the blistering ointment (Vet. Pharm. 539) should be well rubbed in for ten minutes, or a quarter of an hour, and the action of the ointment will be much increased. When the blistering is completed, the horse should now be tied up to prevent his gnawing or licking. If a neck cradle be at hand, it may also for safety be put on; in which case the head may be let down the third day.

540. A neck cradle for blistered horses is very convenient for other occasions also, when the mouth is to be cleaned, or the eye kept open, or the ears, &c., to be smeared. It is of very simple construction, and may be made by a dozen pieces of wood of about an inch and half in diameter, as old broom handles, &c. These bored at each end admit a rope to be passed through; and as each is passed on, a knot may be tied in the upper part of the pieces of the cradle, two inches above the end, and the cradle will be sick by the horse when it is put on; and the horse will be preserved from bending his head to lick or gnaw parts to be protected. When the lower parts of the legs, particularly of the hinder, require blistering, it is necessary to cover the lower part of the horse in a suitable manner, and particularly as blistering is not overlooked and almost certainly if the back of the heels below the fetlock be blistered. First, therefore, smear this part over with hard or sniet; and afterwards avoid touching it with the ointment. After blistering in summer, the horse is often turned out before the blistered parts are quite sound; in this case guard them from flies by some kind of covering or they may become fly-bitten: and likewise the fourth or fifth day rub into the blistered part some oil or hard to prevent the skin from cracking.

541. Sweating or liquid blisters (Vet. Pharm. 5653) are only more gentle stimulants, which are daily applied to the same part without any of the discussed pain or inconvenience. It is expected; yet as the action is repeated, they are often more beneficial even than blistering itself; as in old strains and stiffnesses.

542. Firing, as requiring the assistance of a skilful practitioner, we shall not describe it, it will be only prudently to point out that it is a more active mode of blistering; and that it acts very powerfully as a stimulant, not only while its effects last as blisters do, but also after its escharotic effect is over, by its pressure; and in this way it is that it operates so favourably in bony exostosis, as splints and spavins; and in this way it is so useful in old laceration weaknesses; because by lessening the dilatibility of the skin it becomes a continual bandage to the part.

SUBSECT. 6. Clystering and Physicking.

543. Clystering should always be preceded by backraking, which consists in oiling one hand and arm, and passing them up the fundament, and by that means to remove all the dung balls that can be reached. The large pewter syringe for clystering is not a useful nor safe machine. A much better consists in a tap made of glass to which may be attached a pig of brass, and a very large earthenware vessel, so that the liquid can be administered at one time. (Vet. Pharm. 6564, to 6565.) The pipe should be previously oiled, by which means it passes more easily: the liquor should then be steadily pressed up; and when the pipe is removed, the tail should be held down over the fundament a little to prevent the return of the clyster.

In some cases of a spasmodic nature, as grips and locked jaw, great force is made by the bowels to return the clyster, and nothing but continuous pressure over the fundament can enable it to be retained. Clysters not only act in relaxing the bowels, but they may be used as means of nutriment when it cannot be taken by mouth; as in locked jaw, wound of the mouth, thrush, &c. In locked jaw, it was observed by Gibson, that he kept a horse alive many days by clysters alone: and by clysters also many medicines may be given more conveniently than by the mouth.

544. Physicking of horses in every spring and autumn, and the less so, as at this time they are generally weak and likely to fall in the change going on in their coats. Nor is it always necessary to give horses physic when they come from the street or from hard work; provided their change be moderately brought about. But on such a removal, it certainly expedites all the phenomena of condition (6425.), and such horses are less likely to afterwards fall to pieces, as it is termed. (6424.) In various methods stated physic is passed, but particularly in crabs, where it is used, I believe, as a salutary, and that these doses of physic are given at one time. It is not advisable to physic horses in very cold or very warm weather. Strong physic is always hurtful: all that physic can do is as well operated by a mild as by a strong dose, and with infinitely less hazard. No horse should be physicke the bowels whose bowels have not been previously prepared by mashing for two days at least before. By these means the physic will work kindly of itself, and there is only requisite. Most of the articles put into the purging balls for horses, to assist the aloe, are useless. Jalap will not purge a horse, nor rhubarb either. Aloes are the only proper drug to be depended on for this purpose, and of all the harses the soothing aloes, Cop. are the best. The skins of these are also not improper, but are thought more rough than the soothing. For formula of purging balls, see Vet. Pharm. 6584.

544. Blame gives the following as the process: —

To make the balls. The horses having fasted an hour or two in the morning from food, but having had his water as usual, give him his purgare, and two hours after other him little cold, if any water, as is often done, by which horses are disgusted from taking any; it may be here remarked that in this particular much error is frequently committed. Many horses will drink water with the chile taken out, provided it be perfectly clean, and do not smell of smoke from the fire, kettles, or spauces; but few, very few, will drink warm or hot water; and still fewer, if it be in the least degree greasy or smoky.
VETERINARY PHARMACOPEIA.

After the ball has been given two hours, a warm bran mash may be offered, and a very little hay. He should have walking exercise as usual, moderate clothing, and altogether he should be kept rather more warm than usual. At noon mash again, and give a little hay, which should be heated at night, giving him at intervals chills and drenchings. On the following morning the physic may be expected to work; which if it do briskly, keep the horse quiet; but should it not move his bowels, or only relax them, walk him quietly half an hour, which will probably have the desired effect. Continue to give mashes and hay, and soon they will be excreted in the course of three hours to support the horse, and give him a cluster of warm water, and rub the belly, as well as walk him out. If the gripping prove severe, give him four ounces of gin half a pint of sound ale, which will soon relieve him. On the next day the physick will probably show itself; if not, recommence it, and keep him severely excreted. In about the third night, give a dose of very strong wine, and in the morning it will move the habit of using it will go clear, and in very moderate quantity, and without any injury. When worms or skin foolishness are present, and mercurial physic is deemed necessary, it is better to give two draughts of calomel in a mash the previous night, than to put it into the purging ball.

SUBJECT 7. Castration, Nicking, Docking, &c.

65.46. The operations of castration, docking, nicking, and that of cropping (which is now seldom practised), all require the assistance of a veterinary surgeon; and it is only necessary to remark of them, that the after treatment must be the same as in all other wounds. To avoid irritation, to preserve a cool temperature and a moderate diet; and if active remedies are taken, to oblivate them by bleeding, &c. &c. It likewise is proper to direct the attention of the agriculturist who attends to these matters himself, that the moment the wound following any of these operations looks otherwise than healthy, locked jaw is to be feared, and no time should be lost in seeking the best assistance that can be obtained. (65.25)

SUBJECT 8. Bleeding.

65.47. Bleeding is a very common, and to the horse a very important operation, because his inflammatory diseases, on account of the great strength of his arterial system, often terminate in a fatal termination, and soon after the increase of the pressure by abstracting blood, which diminishes the momentum of circulation. Bleeding is more particularly important in the inflammatory diseases of the horse; because we cannot, as in the human frame, lower the circulation by readily nauseating the stomach. Bleeding also lessens irritation particularly in the young and phlegmatic, or those of full habit: hence we bleed in spasms of the bowels, in locked jaw, &c., with good effect. Bleeding is general or topical. General, as from the neck, when we mean to lessen the general momentum. Topical, when we bleed from a particular part, as the eye, the plate vein, the toe, &c. Most expert practitioners use a large lancet to bleed with; and when this is not acquired, it is by far the best instrument, particularly for superficial veins where a blow might carry the stream through the vessel. In common hands the beam (fig. 88.), as the more general instrument, is best adapted to the usual cases requiring the agriculturist’s notice. Care should, however, be taken not to strike it with vehemence; and the hair being first wetted and smoothed down, it should be pressed close between the hairs, so that its edges may not be impeded by them. A ligature should be first passed round the neck, and a hand held over the eye, unless the operator be very expert, when the use of the fingers will dispense with the ligature. The quantity of blood taken to any considerable degree of quantity will cause the horse’s sides to be wetted, and in inflammatory diseases, a large horse, particularly in the early stage of a complaint, will bear to lose eight or ten quarts: and half the quantity may be taken away two or three times afterwards, if the violence of the symptoms seem to require it; and the blood should be drawn in a large stream to do all the good it is capable of. After the bleeding is finished, introduce a roasting pin, and avoid drawing the skin away from the vein while pinning, which lets the blood escape between the skin and vein; wrap round a piece of tow or hemp, and next day remove the pin, which might otherwise inflame the neck. In drawing blood, let it always be measured: letting it fall on the ground prevents the ascertaining its quantity, it also prevents any observation of what a quarter, of the blood, which if it form itself into a cup-like cavity on its surface, and exhibit a tough yellow crust over this cavity, it betokens an inflammatory state of body that will require further bleedings, unless the weak nature of the horse happens, from it will stand; but a great deal of good blood is so soon, by the blood stick, or from drawing away the skin too much while pinning up, that the orifice inflames and hardens, and ichor is seen to ooze out between its edges. Immediately this is discovered, recourse must be had to an aide veterinary surgeon, or the horse will lose the vein, and perhaps his life.

SECTION VII. Veterinary Pharmacopoeia.

65.48. The following formulae for veterinary practice have been compiled from the works of the most eminent veterinary writers of the present day, as Blaine, Clark, Lawrence, Peel, White, &c.; and we can, from our own experience also (without, we think, too much loss to the art), recommend the selection to the notice of agriculturists, and the owners of horses in general. It would be prudent for such as have many horses, and particularly for such as live at a distance from the assistance of an aide veterinary, to keep the more necessary articles by them in case of necessity. We have inserted those of horse diseases which are most common, and where the compositions can be depended on, and the uncompounded drugs are genuine and good, one of these is a most convenient appendage to every stable. The best arranged veterinary medicine chest we have seen was in London, at the veterinary laboratory of Youatt of Nassau Street, Middlesex Hospital.

65.49. The veterinary pharmacopoeia for oxen, calves, and sheep has been included in the arrangement. When any speciality occurs, or where distinct recipes are requisite, they have been carefully noticed; it will therefore only be necessary to keep in mind, that with the exception of acid substances and general acids, &c., which no cattle bear with equal impunity with the horse, the remedies prescribed require about the following proportions: — A large ox will bear the proportions of a moderate-sized horse; a moderate-sized cow something less; a calf about a third of those of the previous animals; and the eighth part of that amount for the ewe. It is also to be marked, that the degrees in strength in the different recipes are usually regulated by their numbers, the mildest standing first.

65.50. Alkalies.

1. Ligated antimony, 2 drachms.
   Cream of tartar, 2 ounces.
   Flowers of sulphur, each half an ounce.
   2. Cream of tartar.
   Niter, of each half an ounce.

3. Ethyls mineral.
   Ligated antimony, 4 drachms.
   Powdered resin, each 3 drachms.
   Balsam, 1 drachm.
   In a much, or in corn bran and a little wetted every night, or make into a little ball with honey.

65.51. Tonic Alkalies.

1. Gentian.
   2. Aloe.
   3. Ipecacuanha, in powder, of each 1 drachm.
   Oak bark in powder, of each 1 drachm.
2. Winter’s bark, in powder, 3 drachms. Glycerin, 3 drachms. Having the virtues of both, it will be found to be a useful remedy. Cauterize, 3 drachms.

3. White vitriol, 1 drachm. Glycerin or propylene gumm, 2 drachms. Powders should be well sifted, 1 ounce. Alum, 5 ounces. Mix, and give as a drink.

4. Arsenic, 10 grains. Muzzle, and give in mash or moistened corn nightly.

5652. Adstringent Mixtures for Diarrhoea, and to Soothe the Stomach.

3. The following has been very strongly recommended in some cases, for the laxity of horses and cattle:—

Glycerin, 3 drachms. Epson do., 1 ounce. Green vitriol, 4 grains. Trust, half a pint.

4. When the lax or scouring at all approaches to dysentery or melon grease, the following drink should be freely given:—

Castor oil, 4 ounces. Glue (or saffron, 2 ounces. Powders rhubarb, half a drachm. Prepared opium, 4 grains. Gruit, 1 pint. 5653. Adstringent Balls for Diarrhoea or Pissing Evil.

Cathartic (Japan earth), half an ounce. Alum powdered, half a drachm. Sugar of lead, 10 grains.

Balsam of roses to make a ball. 5654. Adstringent Paste for Throat, Foetid, Red in the Face, &c.

Prepared calamine, 1 ounce. Verdigris, of each half an ounce. White vitriol, 1 ounce. Alum, of each half a drachm. Tar, 5 ounces: mix.

5655. Adstringent Waters for Cracks in the Heels, Wounds, Sprains, &c.

Sugar of lead, 2 drachms. White vitriol, 1 drachm. Strong infusion of oak or elm bark, 1 pint: mix.

2. Green vitriol, 1 drachm. Infusion of galls, half a pint. Mix, and wash the parts three times a day.

5656. Powder for Cracks, &c.

Prepared calamine, 1 ounce. Fuller’s earth, powdered. Pipe clay, do., of each 2 ounces. Mix, and put within a glove and dab the moist surfaces of the sores frequently.

5657. Adstringent Paste for Gout.

Prepared calamine, 1 ounce. Turp. powdered. Chincard, do., each 2 ounces. Yeast enough to make a paste.

To the above, if more strength be required, add of alum and verdigris each a drachm.

5658. Adstringent Wash for Do.

Corrosive sublimate, 2 drachms. Sulphur, 1 drachm. Soft water, 10 ounces.

Take up a mortar in a mortar with the spirit till dissolved, then add the water. This is a strong preparation, and has often proved successful in very bad cases of gout, which have resisted all the usual remedies.

5659. Blinders.

1. A general one.

Cantharides powdered, 2 ounces. Venice turpentine, do.

Rub it on the horse’s eye, and then allow it to dry. After the latter the three latter articles together with a damp cloth on the eye.

5660. A strong cheap blister, but not proper to be used in fevers or inflammation.

Oil of vitriol, 1 scruple. Spanish flies, 6 ounces. Palm oil or lard.

Mix of each 1 half. Oil of turpentine, 3 ounces. Mix the resin with the half or palm oil. Having previously mixed the oil of vitriol with an ounce of water gradually, as gradually add this mixture to the melted grease; which again set on a very slow fire for ten minutes more; after which remove the whole, and when beginning to cool, add the powders previously mixed together.

3. A mercuretted blister for spoile, sprains, and ringworms.

Of either of the above, 4 ounces. Corrosive sublimate, thinly powdered, half a drachm.

5661. Strong Liquid Blister.

Spanish flies in gross powder, 1 ounce. Oil of orrisroot, 2 drachms. Oil of orange, 1 ounce. Olive oil, 2 ounces. Neat the stings, in the turpentine three weeks, strain off, and add the oil.

5662. Mild Liquid or Sweating Blister.

Of the above, 1 ounce. Olive oil or goose grease, one and half a drachm.

5664. Clysers, a Laxative one.

1. Thin gruel or broth, 5 quarts. Equine or common salts, 6 ounces. Mix, and give.

2. Mixture for the Kytes.

Milk, 6 quarts. Wine, 2 quarts. Mix, and give.

5665. Nutritious Clysers.

1. Thick gruel, 4 quarts. Strong brandy, 1 quart, or 1. Strong broth, 4 quarts. This knead milk, 5 quarts.

5667. Adstringent Clysers.

1. Tripe liquor, or mix boils milk, 3 pints. Strong gruel, pint, 2 pints. Linament, half an ounce.

2. Alum whey, 1 quart. Boiled broth, 2 quarts.

5668. Cordial Balls.

Gentian powdered, 4 ounces. Ginger, do., 2 ounces. Coriander seed, do., 1 ounce. Cinnamon do., 4 ounces. Oil of aniseed, quarter of an ounce. Milk, 1 quart. Make into a mix with honey, tincture, and give one ounce and a half for a dose.

5669. Chronic Cough Balls.

1. Calomel, 1 scruple. Gum ammoniac, 1 scruple. Horse radish, of each 2 drachms. Balsam of Tolu, 2 quills, each 1 drachm. Beat all together, and make into a ball with honey, and give every morning fasting.

5670. Drink for the same.

1. Ter water. Lime water, of each half a pint. Tincture of equin, half an ounce.

5671. Powder for the same.

5672. Ducrite Balls.

1. Resin, yellow, 1 lb. Nitre, half a pound. Yellow soap, quarter of a pound. Give every morning over a slow fire; when cooling, add the nitre. For a strong dose, an ounce and a half; for a mild one, an ounce. It should be kept in mind, that these remedies are always equal to what is required; and that strong diuretics are always hurtful.

5673. Ducrite Powders.

Yellow resin, powdered, 4 ounces. Nitre, do., 6 ounces. Give 6, 8, or 10 drachms nightly; when some horses readily eat out a mash.

5674. Urine Drink. Glue (or saffron, 2 ounces. Malt, 4 ounces. Dissolve in a pint of warm water.

5675. Embrocations.—Curing for Inflammations.

Goat’s milk, half an ounce. Spirit of wine, 1 ounce. Soft water, 1 quart.

5676. For Sweats.

2. For the Fats.

Sugar of lead, 1 drachm. White vitriol, 2 scrupules. Water, 1 pint.

5679. Fever Powders.

1. Tartar emetic, 2 drachms. Nitre, 5 drachms.

5680. Fever Drink.

1. Tartar emetic, 2 drachms. Simple oxymel, 6 ounces. Water, 4 ounces.

2. Simple oxymel, 8 ounces. Milder spirit, 1 ounce. Beer yeast, of each 1 ounce. Sweet spirit of nitre, 1 ounce.

5681. Malignant Epidemic Fever.

1. Milder spirit, 4 ounces. Carbonated waters, 1 ounce.

2. Milder spirit, 3 ounces. Water, 4 ounces. Put the mixed manganese and salt into a basin; then, having before mixed the vitriol and water very gradually, pour them by means of topical, or any thing that will enable you to stand at a sufficient distance, on the article, as the basin gradually. As soon as the fumes rise, retire and shut up the door.

5682. Hog Liquids.

Oil of turpentine, 4 ounces. Tan, 4 ounces. While oil, 8 ounces. This softens and toughens the hoofs extremely, when brushed over them night and morning.

5684. Purging Medicines.

1. Balls.—very mild. Albis, powdered, 6 drachms. Oil of turpentine, 1 drachm.
SHOEING OF HORSES.

Mrld.
Aloe, powdered, 8 drachms.
Oil of tartar, 1 drachm.
Strong.
Aloe, powdered, 10 drachms.
Oil of tartar, 1 drachm.
The aloe may be beaten with treacle to a mass, adding, during the beating, the oil of tartar. All sizes, oil of burnet, cream of tartar, &c. are useless, and only hurtful additions.

6585. Liquid Purge.
Epsom salt, dissolved, 8 ounces.
Cassia oil, 4 ounces.
Very strong mixture of aloe, 8 ounces.
Mix.—The water mixture of aloe is made by heating powdered aloe with the yolk of egg, adding water by degrees; by these means half an ounce of aloe may be suspended in eight ounces of water; and such a paste is useful when a nail cannot be got down, as in a broken nailed jaw.

6586. Settling Mixture for Pole Evils.
Corrosive sublimate, finely powdered, 1 ounce.
Yellow balsam, 4 ounces.

6587. Foot Steppings.
Horse and cow dung, each about 2 lbs.
Tarr, half a pound.

6588. Wash for Coring out, detumescing,
Ointments, or pronat Haec, &c. &c.
Lunar caustic, 1 drachm.
Water, 2 ounces.

6589. Wash for Monge.
Corrosive sublimate, 2 drachms.
Sperm oil, or linseed, 1 ounce.
Dejection of tobacco, 1 drachm.
Oil of turpentine, of each 1 pint.
Divide the mercury in the spirit, and then add the dejections.

6590. Remedy for Healing.
1. Turner's caure, 4 ounces.
White vitriol, powdered, half a drachm.
Lard, 8 ounces.
Mix, and dose with every morning.

6591. For Buboes.
Sulphur vulgar, 5 ounces.
Arsenic in powder, 2 drachms.
Mercurialis anthracis, 3 ounces.
Tartar, 2 ounces.
Lard, 8 ounces.

6592. For Monges.
Mx., and dose with every morning.

6593. For Scab or Shrub in Sheep, Malters, dext and Sufferers in Horses, and oid Blakes and Eruptions in cattle in general.
Camphor, 1 drachm.
Sparerub and half a drachm.
Mercurial ointment, 1 ounce.

Sect. VIII. Shoeing of Horses.

*6594. The importance of the subject of shoeing to the agriculturist is sufficiently attested by the immense number of inventions which the ingenuity of philosophers and artists are ever day devising, to render the system complete. Almost every variety of horse possesses his favourite shoe; and we find one of the most ingenious of the present day endeavouring to force on our notice, and introduce into our stables, the French method; which is, in the mode of nailing on, that the observer, is the very worst he ever saw. The French shoe, fig. 839, has a wide web towards the toe, and is concave above and convex below (b), on the ground surface, by which neither the toe nor heel touch the ground (c); but the horse will walk much in the same way with an unhappily rather less unlucky boys with walnut shells. But as Blaine observes, in reference to these inventions, "No one form of foot defence can be offered as a universal cure; it is, he continues, that the principles of shoeing are so many, as ought to be those that allow as little departure from nature as circumstances will justify. The practice also should be strictly consonant to the principles; and both ought to consist, first, in removing unuseful weights; and secondly, the bare hoof were applied to natural ground, would remove of themselves. Secondly, in bringing such parts in contact with the ground (generally speaking) as are opposed to it in an unshod state; and also, to endeavour to preserve the original form of foot, or the shoe, in leaving the shoe theroeto; but never to alter the foot to the defence. The shoe at present made at the forges of the most respectable smiths in the cities and large towns throughout the kingdom, if it have not all the requisites, has, however, by degrees, been so improved, that with a few additional alterations, neither difficult to direct or adopt, it is the one we shall hold up as the most eligible for general shoeing. It is not that a better might not be offered to notice; and, in fact, such a one we shall present to our readers; but an average are the generality of smiths from having any improvements forced on them, and so obstinately determined are they to adhere to the forms handed down to them by their forefathers, that their stupidity or malevolence, or both, frequently makes the improvement itself, when seemingly acquiesced in, a source of experimental error. It is too, for these reasons we wear recommendation.

6595. The improved shoe for general use (fig. 840.), is rather wider than what is usually made. Its nail holes (a) extend further towards the heels than is actually necessary for the shoe; by which the expulsion of these parts is encouraged and contraction is avoided. To strengthen the attachment, and to make up for this liberty given to the heels, the nails should be carried a quarter of an inch in front of the shoe (c). The nail holes, of the ground surface of the shoe (a), are usually formed in a gutter, technically called the fulking; but in the case of heavy treading powerful horses this gutter may be omitted, or if adopted, the shoe in that part should be quite even on the foot or hoof surface (b), and not only be rather wider, but it should also have rather more substance than is common; for instance, to have an inch at five eighths, the shoes, according to nature and circumstance, forms a fair proportion; when it is less it is apt, in wearing, to bend to pressure and force out the clinches. A great error is committed in setting shoes out so much wider than the heels themselves, this error has been devised another, which has been that of letting horses go too long without shoeing; in which case, if the heels of the shoe were not too wide originally, as the foot grew, they became lost within the heels; and all the dress, bruises and produced horns; but as we will suppose, that few will wish to enter into a certain error to avoid an uncertain one, so we recommend that the heels of the shoe should stand only wide enough to prevent the expansion of the quarters pushing the heels of the foot over the outer edge of the heels of the shoe; for which purpose, if the iron project rather less than a quarter of an inch, instead of three eights, or even half an inch, as it frequently do, many advantages will be gained. Whoever attentively examines a shoe well set off at the heels, as it is termed, will find only one third of its flat surface protecting the heels; the remainder projects beyond the quarters and treads on; or for the wearer to cut his own legs with; or to afford a more ready hold for the suction of caycey grounds to force off the shoe by. The heels of the common shoe are likewise not in general sufficiently long for the protection of the foot; and which defect, more than a want of width, causes the tendency to press on the crown is firther observed, that if the decreased width of the outer standing of the heels, and the increased width of the web, should make the inner angle of the shoe heel in danger of interfering with the frog, the corner may be taken off. In forging such a shoe, it may be bevelled, or laid towards the inner edge. This shoe is applicable to most feet, is easily formed, and as such, in country places is all that can be expected.

6596. The injuries effects of bad shoeing would only require to be known to excite every endeavour to obviate them; and there are some circumstances in the more common shoes of country smiths that ought
to be impressed on the mind of every agriculturist, and guarded against by every one who possesses a horse. It is too frequently observed that the ground side of their shoe is convex, and that the inward rim, when the foot is on the ground, is the lowest part; on which it is evident the weight must first press; and after being pressed in this manner, the crust of the crust is forcibly driven in, and the resistance offered to its being forced from it, depends on the nails and clinches, instead of its just application to the ground, and the support derived from the uniform pressure of the whole. Every shoe should therefore be perfectly level on its ground surface, nor should any shoe be put on that has not been tried on the horse's foot, and examined in each trial; which, but for this precaution, would be wasted on too many. The substance of the shoe should be the same throughout, forming two parallel lines of upper and under surface; in plain language, the heels, instead of being clubbed as is too frequent, should be the exact form of the foot; and the shoe should be the same in all respects as is usually done; on the contrary, for a perfectly formed foot, the web should present a uniform width throughout.

489. Varieties in form of foot, differences in size, weight, and uses of horses, will necessarily make deviations in the form and substance of shoes. The very shoe recommended may be considered as a variation from what would be immediately necessary, were the feet generally perfect; but it is to be considered that there are but very few feet but what have undergone some unfavourable alteration in their form at the forfeiture of some share of the beauty and delicacy of the animal; for it is recommended that a shoe be used, for general purposes, somewhat wider and thicker than the common one. In weak, tender, flexible feet, it will be found particularly advantageous; and here the benefit of wide heels to the shoe will be most apparent. In such a case as the roads now are, yet most horses are occasionally used to travel on bad ones; some know no other; to those the addition of one, or at the most, two ounces to each shoe is nothing; but the ease to the horse, and its superior covering, as well as support, is inestimable. In very young, very light, and very firm feet, the width and substance may be somewhat diminished at pleasure, and particularly in situations where the roads are uniformly good; but a very long and extensive experience has assured us, that the shoe portrayed is one well calculated to meet the ordinary purposes of travelling, and the present state of the art of horse-shoeing.

488. An improved shoe on the present plan (fig. 811), would appear to unite all the perfections of the modern English improvements, with some derived from our neighbours the French. What has since been called a soled shoe was introduced by Osmer; but from the obstinacy and ignorance of smiths, as it could not be brought into general use until revived by Clark of Edinburgh; by whom it was patronised and recommended. It was finally taken up by Moorcroft, and has ever since attracted some attention, and continues to be employed in some shops where the work is most perfectly done; and where the emphires have liberty enough to pay for such work, and judgment enough to discriminate between its advantages and those of the common shoe. If to this shoe were added the French mode of cutting the sole, we think the improvement would almost shut out all others. On examining the figure it will be seen that this shoe presents a flat surface opposed to the ground (a), which is concave towards the horse’s heel, and which is the concavity does not begin, as in some seated shoes, near the outer edge, but embraces two thirds only of the web, leaving by this means a sufficient surface for the crust; but this bevelling is not intended to reach the heel, for that purpose the web is left square. At this part plain for the heels to rest upon. The great advantages of this sitting are, first, that as the crust rests on a flat surface instead of an inclined plane, as most of the common forged shoes present, its position is maintained entirely, and the inclination to contraction of a great degree avoided. The nailing on of this shoe we recommend to be after the French method, which consists in conical nail holes, punched with a square countersink (d), into which are received conical nails (e); which exactly fill up the countersink; by which means so long as any part of the base of the nail remains, the shoe must be held firmly on, and which is not the only advantage gained; for the nail holes being obliquely formed, and at some distance from the outer rim, act less detrimentally on the crust of the foot.

489. To prepare the foot for the application of the shoe is also an important consideration. Avoid taking off more than one shoe at a time; otherwise the edges of the crust will become broken and jagged, which will retard the shoe being put on. Let the crust be rasped away; after which, the sole should be pared throughout until a strong pressure with the thumb can produce some yielding: too strong a sole tends to heat and contraction, too weak a one will not require paring. In this paring imitate the natural arch of the sole as much as possible; the crust is made to do, from the extreme margin of the foot, but should begin from the inner line of the crust only; by which means the crust, or outer wall of the hoof, will have a firm bearing on the flat surface of the shoe. Let no heated shoe be applied to correct this paring, for that may be left, with a moderate degree of pressure, a smooth, even surface, without hurting the crust, or making it too thin. The portion of sole between the bars and quarters (fig. 836; d) should be always pared out as the surest preventive against corns. The heels also should be reduced to the general level of the foot, never allowing their hardness to serve as an excuse for being left; neither suffer the inner heel to be lowered more than the outer. After all the rest has been done, the frog should be so trimmed as to remain on an exact level with the returns of the heels, and no more. The custom of taking away the point or angle of the horny inclusions of the heels, under the crust, and in the return of the foot to the heels, is the false notion of the smiths, and is to be cautiously avoided. The nailing of the shoe, the putting on of the crust, and the drawing of the knife, is to proceed with the greatest care. The nailing of the shoe should be kept as near the foot of any horse but the largest and coarsest of the cart breed.

600. The shoes for the hind foot are somewhat different to the fore, being a little squarer at the toe and angled a little to which square to the heel is to be given; as the crust is slightly so, avoiding, how- ever, to do it injuriously. By this mode a steady point of bearing is afforded to the hind feet in the great exertions they are often called upon to make in galloping, leaping, &c. They are, when thus formed, less liable to interfere with the ordinary use of the fore shoes by striking or crossing the heels, and it is highly important taillor, rather to shorten the toes of the hinder shoes; but not to do so by the horn; by which, the hoof meets the middle of the fore shoe instead of the shoe itself; and the unpleasant noise of the stroke or click of one foot against the other is avoided.

601. Shoes which necessitate an occasional shaking in showing, or the bar shoe (fig. 812) are the most important variety; and it is to be regretted that so much prejudice prevails against the use of this shoe, which can only arise from its supposed unsightly appearance as betokening unsoundness. As a defence to weak thin heels, this shoe is most particularly proper; it will be found in most part of the preceding remarks; its formation is the same as the others, the crust, however, is made a little higher, and it, to the frog which can well bear it; but a well formed bar shoe should not have its barred part raised into an edge, but such part should be of one uniform thickness throughout the web of the bar, which, instead of being the narrowest, should be the same in breadth as the sole. The lower part of the shoe should be the same as is usual; so as to be adapted to take only a moderate pressure from the frog. When the frog is altogether ulcerated away by thrush, the bar may be altogether plain; but this form of shoe is still the best for these cases, as it prevents the tender surface from being wounded. In corns this shoe is invaluable, and may then be so made as to lie off the affected part, which is the great desideratum in corns.

602. The hunting shoe is made lighter than the common one, and it is of consequence that it is
made to sit as flat to the foot as it can safely do without pressing on the sole; by which the great suction in clayey grounds is much lessened. Hunting fore-shoes should also be as short at the ends as is consistent with the length of the foot, to avoid the danger of being pulled off by the hinder shoes; nor should the web project at all. It is the custom to turn up the outer heel to prevent slipping; which is done sometimes to both fore and hind feet, and sometimes only to the latter. As this precaution can hardly be avoided, or a difficulty to be made of the very slender Swedish iron. Three, or at most four, nails are sufficient on each side; and to avoid the interfering of the hind with the fore feet, the heels of the fore shoes are made short as they can. As racers are shod in the stable, the owners should be doubly careful that the plate is an exact fit. Many pairs ought to be brought and tried before any are suffered to be put on, and this is more important than is at first considered.

6604. Grass shoes or tips are very objectionable placed on the toe sole, in horses turned to grass in summer; at which time they are essentially necessary to guard the fore feet, which otherwise become broken away, and irretrievably injured. They should be looked at occasionally to see that they do not indent themselves into the soles.

6605. Frost shoes (fig. 813) a have the ends turned up to prevent the foot from sliding; unless the turning up or calkin be hardened, they soon wear level and require to be renewed, to keep the entry of the foot by such frequent removals. To remedy this many inventions have been tried; one of the best of these is that of Dr. Moore, in which the frost clip is made distinct and moveable by means of a female screw (b) worked in it, to which a knob or wedge (c) and male screw (d, are attached; key (e) being used for fixing or removing it.

6606. High calkins, or turn-ups, however objectionable in general shoeing, yet, in precipitous counties, as those of Devonshire, Yorkshire, and of Scotland, a are always essential for their draught horses. As it greatly reduces the evils of uneven pressure, if a calkin be also put to the toe; and it would be still better these calkins stecked, particularly the fore ones.

6607. The shoeing of diseased feet is necessarily very various, and is too often left to the discretion of the smith, by which means many friendships are lost, and the evil aggravated, if he be ignorant. The most prominent alterations for these purposes will be found described under the respective diseases of the feet requiring them.

6608. Horse patterns are in use by some cultivators who occupy soft or mossy soils. Those esteemed the best are constructed of elder or elm, and are fixed to the hoof by means of three links and a staple, through each of which passes a leather strap that goes twice round the hoof, and is fastened by a buckle. The staple is placed behind the hoof, the links one way, by the knee, and a half a foot in front, the links being about three inches in length, and rivetted through pieces of hoop iron to prevent the wood from splitting. After numerous trials, it has been found that patterns made in this way answer the purpose better than any other kind. (Farm. Mag.)

Sect. IX. Criteria of the Qualities of Horses for various Purposes.

6609. The general criteria of the qualities of a horse are derived from inspection and trial. His outward appearance among judges affords a pretty just criterion of his powers, and a moderate trial usually enables the same judgment to decide on the disposition to exercise such powers.

6610. The criteria of a horse derived from his colour have been already noticed. (628) As a general principle dark are preferred. In the instance of the hackney, which has its qualities fixed within its range, particularly in the lighter breeds, than any other. Grey horses are also, in some degree, an exception to the rule; for there are many good greys. Bay and brown are always esteemed colours.

6611. The criteria of action are derived from a due consideration of the form generally, and of the limbs particularly; as well as from the horse perform his pace in hand. 6612. The criteria of hardihood are derived from the form of the carcase, which should be circular, or barrelled; by which food is retained, and strength gained to perform what is required. Such horses are also generally good feeders.

6613. The criteria of spirit, vigour, or mettle, as it is termed, are best derived from trial. It should always be kept in mind, that a hot fiery horse is as objectionable as a horse of good courage is desirable. Hot horses may be known by their disinclination to stand still; by their mettle being raised by the slightest exercise, especially when in company. Such horses seldom last long, and under accident are impetuous and frightened in the extreme. A good courageous horse, on the contrary, moves with readiness as well alone as in company; he carries one ear forward and one backward; is attentive and cheerful, loves to be talked to, and caressed even while on his journey; and if in double harness, will play with his mate. Good Courageous horses are always the best tempered, and, under difficulties, are by far the most quiet, and least disposed to do mischief.

6614. The criteria of a race-horse, derived from form, are, that he have the greatest possible quantity of bone, muscle, and sinew, in the most condensed form. There should be a general length of parts to afford scope, sweep, and elasticity, with great muscles hardened by condition, to act on the length of these parts advantageously. As well, his hind limbs should be furnished with ample thighs and broad hocks, which should be low set. His fore-arm ought also to be broad, and the knee, like the hock, should be near the ground.

6615. The criteria of a hunter are, that he have somewhat similar proportions with the racer, but with more bulk to enable him to continue his exertions longer, and to carry more weight. In him, a good carcase is essentially necessary to fit him to go through a long chase; and the more, if he be required to hunt more than one or two days in the week. Some light carcase horses will be a hackney hunter, work a week very well; but, in 10 days, will be very fatigued. The hunter should be well formed in his loin, and well let down in his thighs to propel him forward in his gallop, and give him strength to rise sufficiently to cover his leaps. It is also of great use to a hunter to be a good trotter; many such horses, when fatigued, break out of the gallop and relive themselves by trotting, particularly over heavy ground.

6616. The criteria of a hackney. If it be necessary that the hackney be well formed behind to give him strength, and to propel him forward with ease, so much the more consequence, that he be well formed before; and in this kind of horse the hind parts are in some measure subordinate to the fore, as safety is preferable to speed. The head in the hackney should be small, and well placed on a neck of due length and substance to make a proper appur for the bridle, and that proper resistance to the hand, so pleasant to the feel, and
so necessary for ease and safety. The shoulders should be oblique and well furnished with muscle, but not heavy; and the withers in particular should be high. The elbows should be turned rather out than in, and the legs should stand out straight, and by no means fall under the horse, or it betokens a stumbler. The pasterns should neither be too oblique, which bespeaks weakness; nor too straight, which wears the horse out, and is unpleasant to the rider. The carcass should be round, or the horse will be waxy and weak; the loins straight, wide, and ribbed home; the thighs of good substance; and although the being cat-hammed, or having the hocks turned inwards, is defective in beauty, it often bespeaks a trotter.

6618. The criteria of road horses for quick draught, or coach, chariot, stage and post chaises, &c., are derived from the immediate purposes for which they are intended; as requiring either strength or speed in greater proportions. To make road horses safe, the fore-shafts should be short but quick, which fatigue least. As they approach the hunter in form, they are best fitted for quick work; and as they resemble the best kind of light agricultural horses, they are calculated for heavy draught, as coaches, &c. But in all, a portion of blood gives courage, durability, and condensation to road horses; and the weight of the horse is a consequence to a coach-horse that the neck and head be so formed as to be enabled to retain its beauty to the bridle.

6619. The criteria of a dray-horse are, that he be very broad breasted and muscular, and thick in the shoulders, which should not be turned back, or holding up their heads, such horses may be choked by the collar, as they would, if so formed, draw too much by the throat, and their wind being thus stopped, would be in danger of falling down. The neck of a dray-horse is not the better for being long, and the head should be proportionate to it. Like all horses, he should be chosen with short legs, and good strong hoofs. He ought to be thick in his thighs, and large in bone; but above all, he ought to be a steady collared horse, with courage to make him true to a severe pull; and yet, without a hot fiery spirit to make him fretful.

6620. The criteria of a waggoneer's horse are, in some respects, different from those of the dray-horse. He should have a rather more weighty, and altogether larger. Rapidity of motion is greatly subordinate, in the heavy stage waggoners usually seen on our roads, to strength. It is all collar work; nothing is gained from the momentum of the dragged mass, which, the instant the pull ceases, stands still. The wagoner seeks in the extreme; willing to lie to his collar up-hill, and yet settle into his share of work on level ground. As his exertions are constant, it is of the greatest consequence that he be a good feeder.

6621. The criteria of a horse peculiarly adapted to the labours of agriculture, are thus given by Culley: —

1. His head should be as small as the proportion of the animal will admit; his nostrils expanded, and muzzle fine; his eyes cheerful and prominent; his ears small, upright, and placed near together; his neck, rising out from between his shoulders with an easy tapering curve, and joining gracefully to the head; his shoulder, strong and short, and without the least savage motion in it, should also go into his neck (at what is called the points) unperceived, which perhaps facilitates the going much more than the narrow shoulder; the arm, or fore-thigh, should be muscular, and tapering from the shoulder, to meet a fine, straight, sinewy, and bony leg; the hoof ought to be firm, and laid flat in the shoe, with his chest deep, and full at the girth; his loin or fillets broad and straight, and body round; his hips or hooks by no means wide, but quarters long, and the tail set on so as to be nearly in the same right line as his back; his thighs strong and muscular; his legs clean and fine-boned; the leg-hones not round, but what is called lofty or flat.

6622. A good point in a farm horse is breadth of chest, in the opinion of the author of the New Farmer's Calendar, are, "neck not long, nor too thick; short legs, rather flat than round and gummy; fore-feet felt in not too distant; wide chest; strong, but not high, shoulders; considerable length of waist, support of body by wide forelegs, and full, and rather rather raised to the hip, at least, to the 16th hand high. Being somewhat forelow gives them an advantage in draught; and a moderate length of waist insures speed in the walk.

6623. The horse used in husbandry, according to the writer of the Experienced Farmer, ought to be large, but in other respects like the road horse: and, instead of walking two or three miles an hour, be able to walk four or five. In that case he would be able both to plough more land in a given time, and work in the cart or waggon with more despatch, when worked. In harvest time, a nimble and strong horse is much more desirable for the field, or getting carts of grain into the field, than in account in strength and activity; for, as the draught in all these cases is light one way, such horses would do their business with speed. The small farmer need not with this kind of horse keep an idle one; he might carry his master to market, and plough the remains of both the plough, according to Brown, both strength and agility are required; a dash of blood, therefore, is not disadvantageous. It is not size that confers strength, the largest horses being often the least worn out. A quick even step, an easy movement, and a good temper, are qualities of the greatest importance in a working horse; and the possession of them is of more value than big bones, long legs, and a lumpy carcass. To feed well is also a property of great value; and this property, as all judges know, depends much upon the shape of the barrel, depthness of chest, strength of back, and size of the hips or shoulders, which are sometimes raised too high, or too much, so that the animal is furnished. If straight in the back, and not over short, high in the rib, and with hooks close and round, the animal is generally handy, capable of undergoing a great deal of fatigue, without lessening his appetite, or impairing his working powers; whereas horses that are sharp pointed, flat ribbed, hollow backed, and wide set in the hooks, are usually bad feeders, and soon done up when hard at work.

6624. The criteria of a horse's age are derived from the appearance of the teeth. According to La Fosse the younger, there are these appearances. The horse is foaled with six molar or grinding teeth in each jaw (fig. 844. a); the tenth or twelfth day after, the two front nippers (a) appear above and below, and in

fifteen or fourteen days from this, the two intermediate (b) are pushed out; the corner ones (c) are not cut till three months after. At ten months the incisive or nippers are on a level with each other, the front and a half inch from the gums, and one permanent or horse tooth; at eighteen the crown of the nippers is filled up, and there are two permanent ones; when these are in place at two years (fig. 845.), the first of the colt's molar teeth in each jaw, above and below, are displaced. At two years and a half, or three years, the front nippers fall and give place to the permanent ones; at three and a half the middle nippers are the wise removed, at which period the second molars are found with six molar teeth, five of his new set, and one of his last: at four years and a half the corner nippers of the colt fall and give place to the permanent set.
before was incompletely formed, is now on a level with the rest; at this period the incisive or nippers have all of them a cavity formed in the substance between the inner and outer walls (fig. 844, f), and it is the disappearance of this that marks the age: at six years those in the front nippers below are filled up (fig. 844, e), the tushes (fig. 845, e) are filled up, and the tushes a little more worn (fig. 845, f): at eight years old the corner nippers are likewise plain, and the tushes are round and shortened (fig. 845 g). In mares, the incisive or nippers alone present a criterion (fig. 845, a); at this period the horse is said to be aged, and to have lost his mark; but among good judges the teeth still exhibit sufficient indications. At nine the grooves in the tushes in worn away nearly, and the nippers become rather rounded: at ten these appearances are still stronger: at twelve the tushes only exhibit a rounded stump, the nippers push forward, become yellow, and the age advances, appear triangular and usually uneven.

6522. M. St. Bel, the late professor of the English Veterinary College, used to assert, that after eight years the cavities in the anterior or upper incisive teeth are filled up with equal regularity; thus from eight to ten the front ones were filled up, from ten to twelve the middle, and from twelve to fourteen those of the corner; but though some pains have been taken to trace this, it has been found impossible, as it is the disappearance of the cavities in these teeth is attended with sufficient regularity to warrant implicit confidence.

6527. To make a colt appear older than he really is, both breeders and dealers very commonly draw the nippers, particularly the corner ones; by which means the permanent set which are underneat immediately appear, and the animal is thus fitted for sale before he otherwise would be.

6528. To make a horse look younger than he really is, dealers perform an operation on the horse called budding (from the name of a noted operator); which consists in setting a new set of tushes in the sockets of the old, after the natural one has been worn out by age, by means of a hard sharp tool; which cavity is then burned black by a heated instrument. But no art can restore the tushes to their form and height, as well as their internal grooves. It is, therefore, common to see the best judges thrust their fingers into the horse’s mouth, contenting themselves with merely feeling the tush. To less experienced judges other appearances present themselves as aids. Horses, when aged, usually become hollow above the eyes, the hoofs appear rugged, the under lip falls, and if grey, they become white. In this country, where horses are so easily procured, and where afterwards they continue to be used on hard roads, it is not uncommon to find a horse at six years old feeble, debilitated, and exhibiting all the marks of old age, except in his mouth; on the contrary, when the animal falls into other hands, at ten years of age, without the vigour of youth, and his teeth are the only parts that present an indication of age: it is, therefore, more useful to examine the general appearance of the animal, than to be guided altogether by the marks in the teeth; a too strict adherence to which, Blaine observes, leads to great error on the subject of the age of horses. The commonly received marks, he says, grant not a criterion of a third of the natural life of the animal, nor of one half of the time in which he is perfectly useful. Many good judges will not purchase a horse for hunting earlier than eight years old, and regard him only in his prime at twelve. A gentleman at Dulwich has a monument to the memory of each of three several horses which died in his possession at the ages of thirty-five, thirty-seven, and thirty-nine years; the latter of which was suddenly taken off by a fit of colic, having been in harness but a few hours before.

6531. The general principles of breeding we have already laid down at length (2023), and have here to notice what are considered the best practices in the choice of stallions and mares, and in the treatment of the latter during pregnancy. Unfortunately, however, much less attention has been paid to breeding cattle, although, as Brown has observed, a pound of horse-flesh is worth two of that of any other stock; and it costs just as much to breed a bad horse as a good one. Every one, an eminent writer observes, exercises some degree of judgment in regard to the stallion; but there are few who, correctly retain, who have bred up very ill-formed and worthless mares, and often solely because they are unapt for any thing else than bringing a foal. All the best writers on agriculture reprobate this absurd and unprofitable practice. In the midland counties of England, the breeding of cart horses is attended to with the same assiduity as that which has of late years been bestowed on cattle. There is a great deal of consequence in early care towards its original, so a horse even of the best frame constituted can hardly admit of amelioration, but remains stamped by its original erroneous selection. These remarks, it is hoped, will encourage our breeders to be less indifferent to the choice of their breeding mares.

6532. In those districts where the breeding of horses is carried on upon a large scale and a regular plan, the rearing of stallions forms in some degree a separate branch; and is confined, as in the case of buli
and rams, to a few eminent breeders. These stallions, which are shown at the different towns in the vicinity, sometimes sent to be exhibited at a considerable distance, are let out for the whole season, or sold to stallion men, or kept by the breeder himself, for covering six mares as may be offered, at a certain price; and this estimation according to the rarity of the breed, according as the mare has more or less of what is called blood. For farm mares, the charge for covering by a stallion of the same kind is commonly about a guinea, with half-a-crown to the groom; and it is a common practice, though for a lower rate, to prove with foal; sometimes nothing more is paid in that case than the allowance to the groom.

661. In choosing the parents, or stallion and mare, regard must be had to the kind of stock desired to be bred. Whatever may be the particular purpose of the breed, a stallion ought first to possess all the general properties required for a careful breeder of horses. There are many which may be considered as the characteristics of a horse, whether a male or female, much more frequently acquires and retains the form, make, marks, and disposition of the sire than the dam. On this account, stallions with the least appearance of disease, blemish, or of any kind, and particularly where there is the slightest taint of the filth of the spring, should be rejected as improper. And it is even considered by some necessary to descend to the minutest of symmetry in the head, neck, shoulder, forehead, ribs, back, loins, joints, and pasterns, attending even to a strict uniformity in the form, make, and features of the horse; so that in consequence to an improved selection of both sire and dam, in order to avoid the propagation of vices of temper and disposition of both sire and dam. But provided either parents be free from hereditary infirmities, disorders which arise from accident are of no consequence.

662. The general properties required in a breeding mare, are a good shape, a gentle disposition, a large carcass conformably to her height, and belly well let down; she must be perfectly free from all sorts of blemishes and defects. The size, frame, bone, strength, and blood, will of course be regulated by the purposes of the breeder.

663. The mare which is intended to supply draft draught colts should, according to the author of the Synopsis of Husbandry, be large-limbed, close-jointed, short-bodied, wide-ribbed, with a capacious body; her eyes good, and her nostrils large and open; in disposition she ought to be gentle and tractable. If of a free frame, she is likely to have a vigorous, good temper, and to be a comfort to the husbandry, or any enterprise of theкаж.

664. The age at which horses should be allowed to breed is not determined by universal practice; and is made to depend, in some measure, on the degree of maturity, which, in animals of the same species, is regularly depending on the degree of development. Yet it is necessary for the owner, in some measure, to allow animals of any kind to propagate, while they are themselves in a raw unformed state, and require all the nutriment which their food affords, for raising them to the ordinary size of the variety to which they belong. It may, therefore, be seldom advisable to employ the stallion till he is about four years old, or the mare till she is a year older, and if the stallion be five also it is better, and still more so if he be six or seven. But the greater number of mares left for breeding are not very young; being in many cases not allowed to bring foals till they are in the decline of life, or otherwise unable to bear their full share in rural labour.

665. Three months before a stallion is sexually employed, he should be fed with sound oats, peas, or beans, or with coarse bread, and a little hay, but a good quantity of wheat straw; he should be watered regularly; and continued with good exercise every day, till he is not prepared and in condition, the colts will be likely to be weakly, and the horse himself will become injured, begetting humours, or becoming broken-winded. If he be put to too many mares, he will not last long; his mate and tail will begin to fall off through weakness, and it will be difficult to get up his flesh and strength again. The next year, if the mare is in good order, the number of mares should be increased, till it reaches to the strength and twelve, or at the most twenty, are as many as a horse will well serve for in a season. This number, indeed, is thought by many too few, and in Suffolk, we are informed on the best authority, the stallions serve from fifty to seventy, and even eighty mares in a season.

666. The usual season for the generative process is from the beginning of April to the beginning of July. The month of June is considered the best season in this country; although from the middle to the end of May is more approved of on the Continent, particularly in Normandy, where the farmers devote more attention to this branch of husbandry. In many parts of Europe, the stallions, they have succeeded, perhaps, beyond those in any other part of Europe. This is the time when a mare should be allowed to take the horse, in the different countries, is easily reconciled, in some months with four or five days without, where practicable, is to have her covered at such a period as to ensure abundance of grass, and the return of warm and comfortable weather at the period of foaling. An early colt is always preferred to one that falls late in the season. It is generally understood, and is an opinion that is believed to be well founded, that the mare may be covered on the ninth day after she has foaled, with a greater degree of success than at any other period. This practice is, of course, often followed; but in such cases the mare ought, Donaldson thinks, to be fed in an extraordinary manner, otherwise it is impossible she can do justice to her present and her future foal. But modern farmers would probably, he says, one nearer their purpose, were they to follow the example of the Romans, and content themselves with one foal in the two years.

667. When parturition, there should be a suitable supply of food for the mother and young. The time of covering mares ought, therefore, to be partly regulated by a due regard to this circumstance, and may be earlier in the south than in the north, where grass, the most desirable food both for the dam and foal, does not come so early by a month or six weeks. In Scotland, it is not advantageous to have mares to deliver earlier; and therefore, they are usually covered in May, or early in June. But if mares are intended to bring a foal every year, they should be covered from the ninth to the eleventh day after foaling, whatever may be the time; and these colts will all be bled and brought to the same age again nine or eighteen days afterwards.

668. In breeding horses on a large scale it is easy to contrive so that all the foals may be brought forth at a time when there is plenty of grass. About the end of May the mares are to be put into an enclosure capable of feeding them as long as the stallion is to be with them, or that they are in season. In this enclosure, the mares are to be kept together, as well those which are barren as others. When the stallion's mind shoes are to be taken off, but the fore shoes should be left, or tips put on to preserve his feet; then lead him forth, and let him cover a mare twice in hand, to render him more tame and gentle. After this take him out to pasture, and while he is in the act of courting the mares, being familiar with them, and not soon to return, as it will be frequently the part of the enclosure, and peas, beans, oats, bread, and other good food, put into the manger in it, that the horses may retire into it in the evening, and eat what he likes best. He must be thus entertained during the whole time he is in the mares, which, if the mares are very fat and grass do not hold well; but those which are moderately fat conceive with the greatest success and ease.

669. To bring a mare in season, it is a common thing to give her a quart of hemp-seed, or twice that quantity, night and morning for eight days before she is brought to the horse. If she refuse it alone, it may be mixed with beans or oats, and will go down; and if the stallion eat of it, it will force him also; but it must be remembered that these provocatives are unnatural, and often defeat their own purposes. They
are therefore seldom now resorted to among intelligent breeders. Still more improper is it to attempt an early horning, by injecting stimulating fluids into the vagina as is sometimes done; for when it succeeds, the animal generally suffers so severely as to die of exhaustion.

66. The treatment of a pregnant mare is in general little different from that of any other horse. Mares of draught are worked in summer as usual, and more moderately in the ensuing winter, till near the time of their foaling. In the latter season, though the foal may be so little sufficient for their maintenance, they should be turned out to some grass field near the home-ead, and receive what additional supply of food may be necessary under sheds adjoining. It is both inconvenient and dangerous to confine a mare about to foal in a confined stall, and still more to leave her loose in a close stable among other horses; and confinement is not much less objectionable after dropping her foal.

664. Breeding mares are usually worked through the greatest part of the year, laying them aside only for a week or two before foaling, and then giving suck to the young foal. In this way, Brown observes, the strength and vigour of the mother is not only weakened, but the size and power of the foal stand a great chance of being diminished, by the exertions of the mother when kept at work. Under these improvements, and in considering the workloads, which are generally nothing more than four or five hours pr day, we presume the pupils should have some trouble to remain at ease, to roam upon coarse pastures, where pastures were erected in which they might find shelter during inclement weather, we are almost certain that their progeny would enter upon action with increased abilities. The expense of a breeding mare kept in this way would not be so great as in the case of the mare which has been kept and worked during the whole of her pregnancy, and which are often worked till the very time of foaling. Great care, however, is necessary in working and managing a mare heavily with foal; as she not only has to undergo severe exercise, a fright, or a sudden and violent jerk, are very apt to cause an untimely birth, whereby the foal is lost, and the life of the mare very much endangered.

665. In the mountains of Wales, and in the Highlands of Scotland, the breeding mares are never worked during the summer season, these being turned to the hills and mountains at the close of the barley-seed season, where they remain till the inclinency of the weather forces them to return for shelter. But their scanty subsistence, the labour they are subjected to in procuring their food, and the monotony and coldness of the climate in the latter part of the season, render both themselves and their progeny of but little value and importance.

666. Farms, consisting chiefly of pasture land unfit for feeding, are the situations where breeding is generally carried on. Arable farmers may breed occasionally; but the inconvenience of wanting any part of their arable land, as the crops operate almost as a prohibitory provision against horses. The greater number of horses are bred in situations where a small portion of arable land is attached to farms chiefly occupied with cattle or sheep; or where the farms are so small as not to afford full and constant employment to the number of horses that must, nevertheless, be kept for the labour of particular seasons.

Sect. XI. Rearing of Horses.

6644. Rearing includes the treatment of the foal till it is fit to work, or to be put in training for use, and also the treatment of the mother till she has weaned her foal.

6645. In regard to the treatment of the mare she has weaned her foal in England, and in the improved methods of rearing, as far as possible, the colt is turned, together with the foal, into a pasture field, and is allowed two or three weeks' rest, before she is again worked, either in plough or cart; the foal being allowed to suck at pleasure during the time. After having had a few weeks' rest, she is again worked in the usual manner, the foal being common in the meantime. In Yorkshire, some farmers are particularly careful not to allow the mare to go near the foal, after her return from labour, till her udder has been bathed with cold water, and not till most of the milk is drawn from it. These precautions are used with a view of preventing any bad consequences from the foal receiving over-heated milk. Another practice, and which is superior to the above, is also common in Yorkshire, and in many parts of Scotland: — After the foal is a few weeks old, and has acquired strength and agility enough to follow its mother, it is allowed to attend her in the field during the hours of labour, and to return with her at night. By this mode of management the foal receives a sufficient quantity of milk to compensate any prejudicial effect happen from the over-heated state of the milk, as the foal is allowed to draw it off repeatedly, and at short intervals; but the little animal becomes hardy, and loses all timidity, and afterwards requires no particular allowance of warm food, even in the coldest weather. Generally, the foal is allowed to suck its dam, which is usually about six months; that is, from the time of foaling till Michaelmas, which is the period at which foals are generally weaned, or prevented from sucking. Breeding mares are evidently unable to endure the fatigues of motherhood after parturition, and yet, if their young be not allowed to thrive on cow-milk; but the practice is neither common nor likely ever to become so; and as it is a philosophical fact, well established, that all animals partake, in some measure, of the nature of their foster parent, so there is great reason to fear this practice would prove injurious to foals so reared.

6646. In weaning the foal at the end of six or seven months, great care should be taken to keep the mare and foal from the hearing of each other, that neither may fret or pine after the other. The best method will be to confine the foal in a small stable by itself, which should be furnished with a rack and manger, where it may be fed with clean shaken hay, and clean sifted oats, bruised a little in a mill, or chopped carrots, or boiled potatoes. With this management, he will quickly forget his dam, and become gentle and familiarised to his keeper, and in fair weather may be suffered to exercise himself in a pasture adjoining to the stable; but this should only be for a short time in the middle part of a sunny day; the temperamental nature of the young animal renders it dangerous to keep him out in the night.

6647. The treatment of weaned foals in England, is to put them immediately into a good fresh pasture, where they remain as long as the winter continues moderate. On the approach of winter, they are fed with a mixture of hay, which is always hung in the field for them, as well as the common hay, which they have free access at all times. The next summer they are put into other pastures, commonly the most indifferent on the farm, where they remain till the beginning of the following winter, when they are either allowed to range in the pasture fields, or brought home to the straw-yard. The inclemency of the weather, in the west of Scotland, in England and the north of Ireland, from the fall of snow which generally take place, render it necessary always to house the foals there during that season.

6648. During the first winter foals are fed on hay with a little corn, but should not be constantly confined. It is also best to be on the watch, when foaling to be got on the kids, it is much in their favour to be allowed exercise out of doors. A considerable proportion of succulent food, such as potatoes, carrots, and Swedish turnips (oil-cake has been recommended), should be given them through the next winter, and beans and peas have been added to the usual food, but which, however, inconsiderably, are injurious to the thriving of the young animal, from their heating and astringent nature.

6649. During the following summer their pasture depends upon the circumstances of the farms on which they are reared. In the second winter they are fed in much the same manner as in the first, except that straw may be given for some months instead of hay; and in the third winter they have a greater allowance of corn, as they are frequently worked at the harrows in the ensuing spring. (General Report of Scotland, vol. iii. p. 183.) When about three years old, the author of The New Farmer's Calendar advises...
foals to be fed all winter with a little corn twice a day, with hay, oat-straw, &c. Where carrots can be procured, they form a most excellent feed for colts of every age, on which they will thrive surprisingly. With the most careful feeding, the colts will require them all the time, unless some special cause necessitates, necessarily, a more stimulating diet. Care should, however, be taken to cut them properly, allowing a well littered shed, or warm straw-yard. Colts fed at home with green meat, cut during summer, should have a daily range on a common, or elsewhere, for exercise. Yearlings to be carefully kept separate from the milch mares.

650. The time for gelding colts is usually the same in both parts of the kingdom, which is, when they are about a year old; although, in Yorkshire, this operation is frequently suspended till the spring of the second year. At this period they are sufficiently strong to keep them going, and to prevent their running away, till the following season. Parkinson disapproves of delaying this operation so long, and recommends switching the colts, a practice well known to the ram-breeders, any time after a week old, or as soon after as the mother will allow it. He says, he has followed himself with great success, Parkinson on Live Stock, vol. ii. p. 74.) Blaine's remarks on the subject of castration appear worthy of notice: he says, when the breed is particularly good, and considerable expectations are formed on the colt, it is always prudent to wait till twelve months: at this period, his fore parts are correspondent with his hind parts, but if he be not sufficiently grown, he would stand a great risk of the neck breaking, and his shoulders spare, he will assuredly improve by being allowed to remain whole six or eight months longer. Another writer suggests for experiment, the spaying of mares, thinking they would work better, and have more value than geldings. (Marshall's Yorkshire, vol. ii. p. 121.) But he does not appear to have been aware that this is by no means a new experiment: for Tusser, who wrote in 1562, speaks of gelding fillies as a common practice at that period. The main objection to this operation is not that brood mares would become scarce, as he supposes, but that, by incapacitating them from breeding in case of accidents, and in old age, the loss in this expensive species of live-stock would be greatly enhanced. An old or lame mare would then be as worthless as an old or lame gelding is at present.

651. The training of horses is carried on in places in so systematic a manner, as to combine the profit arising from animals, and the advance in the value of the same, and to ensure the surest test, as to whether they are fit for the purposes to which they are ultimately destined. In the midland counties, the breeders sell them while yearlings, or perhaps, when foals; namely, at six or eighteen months old, but most generally the colts are most brood colts bought by the grave breeders, and other grassy pieces of the midland counties, where they are grown among the grazing stock until the autumn following.

At two years and a half old they are bought up by the arable farmers, or dealers of Buckinghamshire, Berkshire, Wiltshire, and other western counties, when they are broken into harness, and worked till they are three or four years old. At this age they are sent to London, where they are finally purchased for drays, carts, waggons, coaches, the army, or any other purpose for which they are found fit. (Marshall's Economy of the Midland Counties, vol. i. p. 311.)

652. The County of Scotland, is a great producer of transport horses, far more so than any other part of the British dominions. The farmers of Ayrshire, and the counties adjacent, who generally grow corn on not more than one fourth, or at the most, one third of their arable land, and occupy the remainder with a dairy stock, purchase young horses at the fair of Lanark and Carwath before mentioned; work them at the harness in the following spring when below two years old; put them to the plough next winter, at the age of two and a half, and continue to work them gently till they are five years old, when they are sold again at the Rutherglen and Glasgow markets at a great advance of price, to dealers and farmers from the south-eastern counties: or to harvest waggons, horse-drawn drays, and for rent. Horses, however, are the common stock of the farmers in Lothian, or Lothbourgh, the very high prices of late having rendered it profitable to breed them, even upon good arable ground; but many farmers of these counties, instead of breeding, still prefer purchasing two or a half year old colts, at the markets in the west county, or at Newcastle fair, in October: they buy in a certain number yearly, and sell an equal number of their work horses before they are so old as to lose much of their value. (General Report of Scotland, vol. iii. p. 182.)

Sect. XII. Training of Horses.

653. Horses are trained for various purposes, but principally for carrying our persons or drawing our burdens. Formerly, burdens were principally borne on the back by pack-horses, but the improvements in mechanicks have removed them in a great measure back to the front, and the harness has thus become applied over the person of the horse. Under saddle, we train horses as racers, hunters, hackneys, or troop horses. In harness we use them in coaches, stages, chariots, and various lighter vehicles, or we employ them in waggons, drays, chariots, and various other purposes. Horses are said to be ridden or driven in obedience by means of bridles, with appendages called reins, which are long or short, and used in riding or driving. Horses are directed and urged forward by whip, spur, and language, and they are chastised by the same means.

654. The directive language used to horses ought to be every where the same, which is the more easily accomplished, as words or phrases are sufficient for giving every requisite direction to a horse. The first of these words may be "on," or "go on, or merely the common chuck of the tongue, &c. as used by all cockerels, being a most advantageous word, to make the horse go to the right hand side; "right-hand," the third, to the left-hand side, "left-hand;" the fourth to make them stop, may be "stop," or "stand still." Any attempt to modify these directions ought to be given in the correct language of the country, and not in provincial words. be on, go on, slowly, briskly, right-hand, a little round, or turn, left-hand, a little, or left-hand and round, stop, or stand gently, &c. As a proof that only four words are requisite for giving every requisite direction to horses, we may mention that foreigners in Stockholm, Petersburg, and Moscow, who know nothing of the words, require only four corresponding words of Swedish or Russian to direct their coachmen and sledge drivers to any street, house, or place, the situation of which they know by the maps, or otherwise.

655. The three natural and ordinary movements of horses are, walking, trotting, and galloping, to which are added, walking, or ambling, &c. which is known by the name of "an schooling," or "paceing." The trot is, perhaps, the most natural motion of a horse, but the pace, and even the gallop, are most easy to the rider.

656. In training saddle horses, the first thing is to make them familiar with man, and other general objects, and which is best effected at the earliest periods, when they are naturally active, and docility follows as a matter of course: to effect this, the greatest kindness should be used to the colts from the moment they are dropped: they should be accustomed to be handled, should be fed with tenderest care, and ought not to be caressed. It is necessary that they have light meals, and that the food of different colours and forms should be shown them with caution. While at foot, the mare and foal should be led out into roads, and where carriages pass, during which time nothing should be allowed to interrupt them. By this management, the animal will be fully prepared for the future operations; and it is thus that the single foal the ploughed-ground farmer breeds, and which daily follows the mother in her work, as it were breaks itself.

657. Bucking is the next operation, and if the colt has been judiciously used, and taught familiarity and caution, he will do very well: but it should be commenced when the colt is two and a half or three years old. The first bucking of a horse is a thing of great consequence, as his value afterwards very much depends on it. The application of the saddle should be gradually done, and the horse having been used to the saddle and brisk, and has been exercised some time, morning and evening in it, and become somewhat obedient, it is usually
recommended that he be taken to some ploughed land, where he is to be walked and trotted until he be slightly fatigued. If the colt be very high spirited or refractory, or if he be not inclined to lift up his legs sufficiently, walk him on some very light ploughed land; but if otherwise, it is better to dispense with this, and a field and a road alternately used will, in general cases, be found preferable. It would be well that this preliminary practice should be performed in a cavesson to ensure obedience.

Then let by degrees, let a person sit on the colt, and exercise him by degrees across his back; and if he seem not to be alarmed, let him proceed at a foot-pace with his burden. When this occasions no alarm, let one leg gradually be slid over his back, the person at his head engaging his attention during the time, and encouraging him. This may then gradually advance, the other leg, in the same manner, being doubled across his back; and if this be trotted in the hand over the same ploughed land or other ground again, till he is more fatigued, and willing to receive the rider quietly on his back; when this is done, the person who is on his back must encourage him, and the man who has his head, all of them keeping a proper degree of spirit, the feet are to be fitted well in the stirrups, and the toes turned out; afterwards the rider is to shrink and move himself in the saddle, and the person who holds his head is to withdraw his hand a little farther from the mouth. As the rider moves his toes forward, the holder must move him forward with his weight, and making him stand still when desired. In this manner, by sometimes following, and sometimes going before another horse on the trot, the creature will by degrees be brought to know that it is his business to be quiet and governable.

To teach a horse the different movements of walking, trotting, galloping, and ambling, comes next in order.

Walking is the slowest and least raised of all a horse's movements. It is performed, as any one may observe, by the horse's lifting up its two legs on a side, the one after the other, beginning with the hind leg first. Thus, if he leads with the legs of the right side, the little fore foot is lifted up, and placed on the ground; and in the time he is setting it down (which in a step is always short of the tread of his fore foot on the same side) he lifts his far fore foot, and sets it down before his near fore foot. Again, just as he is setting his near fore foot down, he lifts his hind foot, and sets it down again; and just as he is setting his hind foot down, he lifts his far fore foot; and just as he is setting it down, he lifts his near fore foot, and sets it down beyond his far fore foot. This is the true motion of a horse's legs in a walk; and this is the pace in which many things are best taught; for instance, when the horse is to be taught to turn to the right and left, or from one to another of the two great roads on the trot, and to turn on the gallop. The walk is a pace to which team, carriage, and road horses should constantly be well broke, as being of great use in all such cases and intentions. It is an excellent pace too in a saddle horse, when well performed by being properly taught.

Trotting, the limbs are diagonally employed; but their tenses or times, or rising and falling, are very different, as it is conducted slow or fast. In the slow trot the diagonal legs are elevated and replaced simultaneously; while those on the ground are preparing to elevate themselves, and the horse is moved in a moment on foot; and until the original diagonal legs are set down, the horse's movements are not wholly elevated; therefore the horse is during the moderate trot at no time without support. But it is very different when the trot is accelerated, as to nine or ten miles an hour; for then there is a period in every spring made by the diagonal members, when all the feet are in the air at the same time; and the body completely suspended from the ground by these members. When this accelerated motion occurs, the off fore leg and near hind leg having been elevated in the air, before they meet the ground, the near fore leg and the off hind leg are not only prepared, as in the slow trot, to elevate themselves, but actually do so before the others are set down; and the horse consequently, the feet, at this precise time, must be all in air. (fig. 846.) To speed in the trot, it is necessary that a horse puts his feet quick, and draws his fore foot forward. To the safety also, it is necessary he elevate his knee particularly at the same time the general elevation of the whole limb is operated by high withers and oblique shoulders.

Three qualities are essentially necessary to make the trot useful. It ought to be extended, supple, and even, or equal: these three qualities mutually depend upon each other, so that you cannot pass to the supple trot without the extended trot; or, without the supple trot, you can never attain the equal trot. The extended trot (fig. 846) is that in which the horse trots out without retaining himself, going directly forwards; and this consequently is the kind of trot with which you must begin. The supple trot is that in which his head and neck, as is the case in the other, are perfectly straight, and his organs composing them, which no colts or raw horses can execute, who have not had their limbs supplied by exercise. The even or equal trot is that in which the horse moves so equably and exactly, that his legs never cover more ground one than the other nor at one time more than another. To go from the extended trot to the supple, you must gently and by degrees hold in your hands, and when by exercise he has attained sufficient ease and suppleness to manage his limbs readily, you must insensibly hold him in still more and more, and by degrees you will lead him to the equal trot.

The manner of trotting a colt who has never been backed is as follows:—Put a plain snaffle in his mouth; fasten a cavesson to his nose, to the ring of which tie a longe of a reasonable length. Let a groom hold this longe, who having got at some distance from the colt, must stand still in the middle of the road, or with a longe or chain there in his hand. The cold being alarmed, will be forced to go forward, and to turn within the length of the cord, the groom must hold it tight by his hand; in this means he will draw in, or towards the centre, the head of the colt, and his croup will of consequence be without the circle. In working him against your young horse and making him hard press him and afterwards put him to the trot. If you neglect this method his legs will be embarrased; he will lean on one side, and be more upon one haunch than the other; the inner fore foot will strike against the outer one, and the pain which this still occasion extenuates him to seek some means of defence, and make him disobedient. If he resists to trot, the person who holds
The gallop is the swiftest natural pace of a horse, in which the two fore feet are elevated almost at the same moment, but one slightly takes the lead of the other, and must therefore be set down before the other has left the ground. This pace has an indirect and also a direct precedenct in the leg of that side which has been led by the fore. Such is the natural gallop of a horse, when it is performed with its utmost velocity the limbs are simultaneous and synchronous.

In galloping the horse may lead with which fore leg he pleases; the most usual way is that with which the horse is accustomed to lead; but if it is desired to make the horse gallop to be led to the right side, it must follow next, which forms an even or equal gallop; otherwise the legs are said to be bedissimulated, and the gallop to be false; to remedy which disorder, the rider must stay the horse a little on the hand, and hold on more on the control, which is of service to that contrary leg, which has been always strictly observed; for hunting horses have been trained to lead indifferently with both legs, because it has been found, that a horse which has never been suffered to gallop but with his right fore leg, has been worn out on one side, when he has been fresh and sound on the other. In order to make a stop in a gallop straight forwards, the rider should carefully put his horse together, without altering the distribution of the appui, and throw his body back a little to accompany the action, and to relieve the horse's shoulders. In doing this he should seize the time of making the stop, keeping the hand and body quite still, exactly when he feels the horse put his fore feet to the ground, in order that by raising them immediately by the next motion which he makes, he may be upon his haunches. When horses do not answer to the lessons in the gallop, they should be galloped briskly, and then slowly again by turns, and they will thus be compelled to obey the hand and heel. In the slow gallop, as well as in the trot, it is sometimes necessary to close the heels to the horse's sides, which is called pinching; but this should be done in such a manner as not to make the horse abandon himself upon the hand and rear, and must be taken that he be upon his haunches, and not upon his shoulders; and therefore, when he is pinched, he should be stopped. To put a horse together, and bring him to the gallop, the rider must close his legs upon him, putting them very much back; this will oblige him to slide his legs under him; at the same instant let the hand be raised a little to support him before, and yielding again immediately, let him be supposed to have stopped from time to time, till he begins to play with his haunches, and the gallop is increased and sits down, he then presses with the calves of his legs, and he will thus become quick and sensible to the touch. If a horse has too fine a mouth, gallop him upon sloping ground; this will oblige him to lean a little upon the one better, and the horse will be brought to the hand, and the fore and hind legs will be prevented from resisting the operation of the bit. If the horse is heavy in hand, gallop him up sloping ground, and when his appui is too strong, this will lighten him. The gallop serves to assure and unite the parts of the body, to make them supple, and flexible, and to give the legs to both the fore and hind limbs. (Berenger's History and Art of Horsemanship, vol. ii, p. 104, &c.)

In galloping in a circle, the horse is confined always to lead with his fore leg within the turn; otherwise he is said to gallop false.

The varieties of gallop may be reduced to the gallop of speed, the ordinary or hand gallop, and the canter; all others are but compounds of these. The gallop of all speed is the most simple of all the paces, being nothing more than a succession of leaps; but it requires repeated efforts to acquire its full extent, and it is being chiefly employed in the transport of goods and thoroughbreds, and as the velocity increases, the fore and hind legs become opposed to the ground at almost the same instant, thus forming a repetition of leaps. The ordinary or hand gallop does not differ from the gallop as (665), except that the leading leg being elevated still earlier, and being carried still more forward, is followed also by an earlier and a more considerable displacement of its fellow leg behind, which of course retards the velocity considerably, and lessens the exertion. The school gallop is formed of this, with the haunches drawn more under, and the fore hand more thrown up.

The pace is different from the gallop in some essential particulars. Whether the gallop be fast or slow, still the legs are at one period wholly removed from the ground, and the horse is all in air. In the canter, on the contrary, at no period is the horse completely elevated from the ground, but has always one or more points of contact with it. Blaine describes its operation thus:—When performed on the right, the horse has the hind leg first placed, and a little hind leg is set upon the ground, which elevates the fore hand, and places first the near fore leg on the ground; the off doubling over and beyond, is placed in an instant after it. In the next movement the hind legs are thrown in, and, while elevated, the shoulders become raised out of the ground; but if this is not elevated until the hind ones are replaced. The near fore leg is, therefore, the whole point of support in cantering at each remove, and thus it is that cantering horses always first fall on that leg.

The canter is a peculiar kind of pace, by which the horse changes sides at each remove; two legs of a side being always in the air, and two being when they are two, and thus granting to walk when they are of three years' growth. They should be placed under the charge of a very steady careful servant, who

The training of cavalry horses is exclusively performed in the military establishments, and therefore not to be required of the farmer or breeder.

The training of coach horses commences with walking, trotting, rolling, and repeated longeing; and next with yoking and driving in a break or four-wheeled frame, with no other load than that of the coach box or seat placed in the usual position, the driver and his assistant sitting on a board fixed to the proper place; when the horse is caught by a momentary side, Coach horses, from fifteen to sixteen hands high, should walk; light six miles an hour, and trot twelve. They should be first accustomed to this exercise in the country, next in the outskirts of a large city, and lastly in the most crowded streets.

The age at which a horse is fit to be worked in a coach is four and a half or five years; but by the fraudulent practice both of the country and town dealers, horses of three and four years old are frequently employed. The first business of the Yorkshire dealer, who has three or four years old colts to dispose of, is to mark the points on the inner teeth, in order to make them thereupon the operation of docking and nicking, and after having been kept two or three months on mash, made of bran, ground oats, or boiled corn, they are sold to the London dealers, who, it is said, sell these three or four years old colts for two guineas. The cutting of the teeth over five years of age is considered for the coach or saddle; and in a few months are completely destroyed by this premature and too severe labour. The drawing of the teeth is not a fraud practised on the London dealers; they know the deception, and insist upon it being done by the country dealers. It is requisite to be done some months before the animal is to be used for the coach or saddle, or the teeth of a horse to be five years old would not be good, consequently the drawing of the deception could not have been practiced.

The training of cart and plough horses commences with taming before they are one year old, with which it continues as if the animal is not added to the plough or collar until three years of age. They should be placed under the charge of a very steady and careful servant, who...
will teach them to back, and to go into the shafts. They ought not, however, to be made to draw any other than a very light empty cart till their fourth or fifth year; nor ought they to be put into the shafts of a threshing machine before their fifth year. The first work to which an agricultural horse may be applied is harrowing; but this during the fourth year only half a day at a time, or with a light harrow the whole day. Next he may be put to ploughing, provided subjects a similar care as the plough. With the general, agricultural horses require very little training; but one thing is too often neglected, and that is, teaching plough horses a quick step, and keeping them at that step ever after in working them. By not attending to this, and leaving the step to be regulated by lazy spiritless ploughmen, the loss to many farmers is very considerable.

SEC. XIII. The Art of Horsemanship.

6671. Horsemanship, as an art, is unquestionably of very ancient date, and it is curious how very different are the modes by which it is practised in different countries; but which differences are yet principally confined to the action of the feet of the rider, for whilst the horse is generally practised, it is by the rider placing himself astride the animal. Horses were used in this way for centuries before any apparatus was used or applied to their bodies to spare fatigue to the rider; and we know that the first saddles were mere pads strapped round the body, but without the appendages of the shabraques. In England, riding is systematically divided into two kinds, which are manege and jockey riding.

6672. Manege riding, called also riding the great horse, in the strict application of the term, was formerly more practised than at present; and required a system of education for both horse and rider long and severe. Horses perfectly broke for the manege are formerly taught several paces and motions, as ambling, parading, passing, yerking, capriole, and cornetti. The practice of these artificial cadences, it is supposed, injures the natural pace of the horse; and this circumstance, united to a particular form of horse (defective for other purposes) being required for the elasticity of the action of these actions, has tended to bring manege riding, as formerly practised, into disrepute. Manege riding also taught the constant application of the seat of the body of the rider to the seat of the saddle, during all the motions of the horse; and as a severe education, and a particular form, had bestowed ease and elasticity to the readiness of the manege horse, the inconveniences of that form were not felt. Therefore, when good specimens of excellent roads, was in general use, this kind of riding was found hurtful to both horse and rider; fatiguing the one, and injuring the other.

6673. The art of proper riding, as practised among experienced horsemen, is derived from a knowledge of the judicious application of the aids of the bridle, as taught in our schools, and as practised in the army generally; and also from a proper application or placing the body on the horse. These we certainly owe to manege riding; and a knowledge of them is as essential to the safety of the rider, as it is to the greatness of the horse.

6674. The use of the cub bridle is considered in the schools to be essential to good riding: by it the horse is not only restrained, but he is also aided and assisted. He is alternately thrown on his hand or checked by the bit, in great variety, however, is required in the use of the cub; and without an inclination and ability to use it lightly and dexterously, a snaffle is the best and safest cub. The curb is to be operated by a gentle turn of the wrist only; and the action of the hand in this respect should be so free and easy as to be pliable as the fingers on a rod and line. The force of the curb should in every instance be proportioned to the mouth of the horse.

6675. The best form of saddle for general riding is one in which the cantle is not so high as the military, nor so low as the racing saddle. The pommel should be no more round than necessary to keep it free from the withers. The stirrups should be substantial, not only to prevent breaking, but also that they may be fast to the foot when accidentally slipped away; which is of more consequence than at first sight may appear; if they are of the spring kind, it is also desirable: but it is still more desirable, that the spring stirrup leather should be used, which prevents the danger arising from horses catching the leather in the projections of doors, gates, &c. Having saddled and bridled our horse, we will proceed to mount our rider.

6676. If you would mount with ease and safety, says Hughes, stand rather before the stirrup than behind it, with both the hand and the right hand, and the mane together, help yourself into the stirrup, with your right, so that, in mounting, your toe do not touch the horse. Your foot being in the stirrup raise yourself till you face the side of the horse, and look directly across the saddle; then, with your right hand, lay hold of the hinder part of the saddle, and, with your left hand, take hold of your horse's tail, and let your hand rest on your shoulder; and let your body be in

6677. A graceful and proper seat on horseback is greatly dependent on a right disposition of the legs and thighs, which the judicious application of the aid of the stirrup, and the opening of the knees, whereby the fork will come lower on the saddle. (Fig. 846.) The thighs should be applied to the saddle and to the sides of the horse by their inner surfaces, so as to bring in the knees and toes; and although the line of the canes be properly broken by some irregularities, yet the foot, the knee, the hip, and shoulder, should deviate but little from one perpendicular line. The ball of the foot should rest within the stirrup, and should be even with the heel, or very slightly elevated above it. Avoid any stiffness in the thighs, or any pressure on the body; all the force should be in the legs, and the horse, either for support, or as aids to him. The loins, particularly, should be lax and pliable, as a coachman's on his box; and for the same reasons: for by sitting thus loosely, the rough motions of both are more amenable to the benefit of a true equipage of body, and is rather to stick on a horse than to sit on it.

6678. When you are troubled with a horse that is vicious, which stops short, or, by rising or kicking, endeavors to throw you off; you must not bend your body forward, as is common; but you must place your feet straight in, and force your arms and legs, together with the hand, which motion throws the breakc back, and compels you to reposition your leg. In case he should throw his head, you must yield to his motion, and throw your body backwards at the same time you frequently save a horse that would otherwise fall.
to recover it when lost, is to advance the lower part of your body, and to bend back your shoulders and upper part. In flying or standing leaps, a horseman's best security is the bending back of the body. The rising of the horse in the leap should affect the rider's seat; he is chiefly elevated by the motion of the legs, which is best done by inclining the body backwards. But the usual method of fixing the knees in all cases or danger only serves, in great shocks, to assist the violence of the fall. To save yourself from being hurt, in these cases, do not allow your horse to take the leap unless you have little to the horse's head, and when you will recover your seat, if displaced, or keep it at such times as would dismount an unskilful horseman.

6639. If your horse goes wrongly, take the reins separately, one in each hand, put your arms forward, and hold him short, but do not pull hard with your arms low; for, by lowering his head, he has the more liberties to throw his heels out of the stirrup, and set his tail rising behind. Is it not reasonable to imagine, that, if a horse is forced towards a carriage which he has started at, he will think he is obliged to attack or run against it? Can it be imagined that the rider's spurring him on, with his face directed to it, he should think it proper to sign to pass it? These rational queries are submitted to the serious consideration of such as are fond of always obliging their horses to touch those objects at which they are, or affect to be, frightened.

6639. Enlarging horses, Lawrence observes, undertake venture on horseback without spurs. Those who reflect upon the predication of being placed between a deep ditch and a carriage, at which their horse shies, will see the necessity of this precaution.

6639. Previously to mounting, every person will find his account in examining the state of both horse and furniture with his own eyes and hands; for, however good and careful his groom may generally be, it is a maxim, that too much ought not to be expected from the head of him who labours with his hands. Besides, all such sedulously avoid trouble, particularly in nice matters. For example, see that your currib is right; that your reins are not twisted; that your girths, one over the other, still bear exactly alike; that the pads be not wrinkled up; but, above all, that your saddle lies exactly level upon the horse's back.

6848. On getting off the horse's back, hold the bridle and mane in the same manner as when you mounted; hold the pommel of the saddle with your right-hand; to raise yourself, bring your right leg over the horse's back, let your right hand hold the hind part of the saddle, and stand a moment on your stirrup; when at last you mounted. But beware that, in dismounting, you bend not your right knee, lest the horse should be touched by the spur.

6848. The jockey mode of riding is practised in its fullest extent in racing. With some modification it is also in use by many who esteem themselves excellent foxhunters. With still greater modification it is by its advocates practised also on the racecourses. English jockeys and young boys unite themselves, perhaps, more frequently with themselves and horses. True jockey riding consists in the use of a snaffle bridle, which is held firmly; and, as an advocate for it expresses himself, to enable the rider to give his horse the strictest exercise. Of such a style of riding the following is a description. To this end you must make yourself firm and strong, and sit correct; and, as you would sit in a chair, with the knees nearly as much bent, and turned inward; the toes somewhat out and upward; the leg falling nearly straight, and the horse foot in the stirrup; elbows close to the sides; hands rather above the horse's withers, or under the pommel of the saddle; and, as a writer on the same subject advocates the jockey mode, by commenting on the decline of riding-house forms, and the universal preference given to exhibition, which, as he says, is perfectly conformable to the superior use and condition of the horse; for, as he adds, the horse-house was, and the riding-house is, preserved by the balance or equipoise of the body solely; that recommended here by the firm hold of the knee, which is obviously strengthened by the opposite directions of the knee and toe, the one in, the other outward.

6848. Section XIV. Feeding of Horses.

6848. The feeding of horses generally is an important feature in their management. In considering the food for horses, we are apt to locate our notions to the matters around us, without taking into account that every country has its peculiar products. Whitley, who found his facts in the works of Linnaeus, and his natural propensities are fitted for the high and partial climates of Persia, Arabia, and the Indies, having been accustomed to feed his horses on hay, bran, and other coarse materials, as a great part of the Arabians, who, he says, are much addicted to the jockey mode of riding. It is curious to observe that in the Indies, and in many parts of the world in these countries, there are no stables, but horsemen are accustomed to take their horses out of doors. They feed them with bread, rice, and other grains, which they are used to eat, and which they can digest with great ease. It is also remarkable that in these countries, they are accustomed to feed their horses with milk, which is a food that is not very common in this country. They are also accustomed to feed their horses with vegetables, such as beets, potatoes, and other root crops, which are very nutritious and digestible.

6848. The food of British horses may be divided into herbage, grain, roots, and mixtures. Of herbage, the green herbage of the field is the proper grain, eaten either fresh or dry; and it is the natural state, such a horse is said to graze; but when these matters are cut, and carried into the stable to a horse, he is said to be fed. Hay is herbage cut during its flowering and seedling processes; which being subjected to the action of the sun and air, a proper time, are then collected into large masses called haystacks. If a certain degree of fermentation takes place before the matter is fitted to become wholesome or nutritious, or before it receives such alteration as its for resisting further destruction and decay. The judicious management of this fermentative process forms one of the greatest desiderations in the art of feeding. Forced hay, or hay made in an improper state, is injurious; to the parts, as the seeds, &c., in conjunction with the heat evolved during the process, as it was mildly the whole, and sugar is produced. Pushed beyond this, the hay becomes carbonized, and mould-burnt; its nutritive qualities are increased, and it is found in this state to excite diabetes, sweating, and extreme weakness and emaciation. (6848.)

6848. The quality of the hay is very little attended to, but which is of very great importance; and more particularly so where little corn but much hay is given. Hay should therefore be of the best, whether meadow, clover, or mixed. Many horses thrive best on very hay, particularly draught horses, and it is very good for horses, as it saves waste of saliva; to sprinkle hay with water has the same effect, but it should only be done as it is wanted.
FEEDING AND watering of horses.

6886. Hay should never be given in large quantities at a time; horses breathe on it, become disgusted, and then waste it. They also, when it is good, eat too much, and distend their stomachs, and then become crib-busters. Hay should not be kept in the stable in great quantities; otherwise it becomes impregnated with dust, and the thistle spoils it. Hay is used, however, when wheat, barley, oats, and rye are used; but these are much less nutritious, and rather serve to excite mastication by mixing with other substances, than to be depended on for animalisation. On hay, when good, many horses subsist; and when no exertions are required of them they are sufficiently nourished by it.

6887. The grain used as horse food is of various kinds, possessing, it is supposed, different degrees of nutrient, according to their different proportions of gluten, sugar, orUnavailable.

6888. Sir Humphry Davy, as we have seen (§ 5000), contains 748 parts of nutritious matter out of 1000. In wheat, 955 parts of 1000 are nutritious; but wheat is seldom given with us except to racers and hunters, or on extraordinary occasions when Governor's augmentation is required, while its consumption is sometimes given in the form of meal. It is more frequently given than wheat, and contains 939 parts of 1000 of nutritious particles. Made into malt, where its sugar is evolved, it becomes still more highly nutritious. Barley appears to have been the principal horse food of the ancients.

6889. The roots used as horse food, the basis of beans, peas, vetches, &c. Beans are seldom given alone on account of their heating and astringent qualities, but are mixed with straw or hay, cut into chaff, either whole or broken.

6890. Mixture, or mixed food, is formed of several kinds among agriculturists; and it possesses many advantages, as it can be varied to every taste, and made either cool or hot, or even steam to stir up and stimulate it. As it is principally used for waggon, post, and farm horses, it is cut short of the rest of the other feeding, one part of the chaff made from one part of the best meadow or clover hay, and two parts of wheat straw; two bushels of this mixture add one bushel of oats. The importance of bruising or flattening the oats is very great. When used whole, the better they are bruised, or the shaft in which they lie, or the teeth drawn through it, and the longer it is given alone, or with chaff, would, in most instances, increase the benefit of bruising. To horses under great exertion, the stomach must be, to a certain degree, weakened also; in such cases, by bruising their corn, not only the work of mastication is much less of it, but that of the stomach also. In old horses with worn teeth, the more coarse parts of the grain are extracted from the excrement of the horses. Of this manner food, three, four, five, or six pecks may be given daily, according to the size and exertions required; and as little hay is required, so hard-worked horses are enabled to lie down much more, instead of standing on their already fatigued limbs to eat hay.

6891. Cooked food is also much used by practical agriculturists for horses. The articles made use of are potatoes, carrots, turnips, or parsnips. To horses with their digestion weakened by hard work, old age, or other causes, food in sufficient quantities, thus already reduced to a pulpy mass, resembling that of whence such nutriment is gained is not a matter of import; but if such exertions are to be combined with celerity, as in our racers, hunters, &c., it is evident that such feeding is best adapted to the end required which combines the greatest bulk; and which by its quality, causes subsistence, and grass, even to the most valuable hackneys, the carriage horses of the wealthy, &c., are accustomed to be fed, not as though their exertions were moderate, but as though they were unceasing, to the destruction of a vast quantity of valuable corn. From thousands of such horses, at least one third of their hay and corn might be advantageously abstracted.

6892. Too great a quantity of food injures not only the community but the horse also. The stomach becomes distended by over-feeding, and it then becomes weak and incapable of a healthy digestion. Habituation to this habit leads, and perhaps when the stomach does digest this undue quantity, it generates fulness, which shows itself in indigestions or flatness, appearing in the form of cracks and gases.

6893. A horse in full work, of whatever kind, will require, according to his size, a peck of sound oats in twenty-four hours; and when the work is unremitting, as in post, stage-waggon, or other very large and hard-working horses, even more may be required. Some post horses have an unlimited quantity given them; but this practice is always erroneous. If they eat more than the stronger digestive powers: if they blow on it they leave it, and it is wasted, or a more greedy one swallow it up without mastication; and both stomach, horse, and master are thereby robbed. It is of consequence that the oats, as an important part of horse food, should be given only sweet, from thirty-eight to forty pounds the bushel. To encourage a slow and thorough mastication, sprinkle them with water and spread them well over the manger. The quantity of hay required for small horses is from eight to ten pounds the twenty-four hours; in corn-fed horses, ten or twelve pounds are not too much. This quantity is also sufficient for carriage or coach horses, as they usually have either corn or mixed food in sufficient plenty also. For waggon and the larger agricultural horses, from fifteen to twenty pounds may be requisite. When it can be divided into four portions. The largest portion both of hay and corn should be given at night; the next in quantity in the morning; the other two portions at noon, and about four in the afternoon. This, however, must depend on the work of the horse, and other circumstances.

6894. Watering of horses is an important part of their management, and many errors are committed relative to it. It is equally erroneous to debar them from it, as to allow too much; and the former is much the most common evil. In summer, or when from great perspiration the animal juices
are wasted, it generates fevers, and wastes the strength and spirits. All horses prefer soft water, and as nature is unerring, there is no doubt but that it is the most wholesome. As some horses drink quicker than others, it is not a good custom to take riding horses to a pond, unless at night, when the quantity cannot injure them; or when not intended for early work the next morning, as hunting, &c. 70. The necessary quantity required for a horse should be considered in the weather, the work, &c. In common cases, a large horse requires rather more than the half of a large stable pail full twice in the day. At night a full pail should be allowed. Horses should never be galloped after drinking; it has destroyed thousands of horses by gorging them, inflammation of stomach, indigestion, &c. If they run home they are to run home directly they are accidentally watered at any time. Others, expect ing, they are to be fatigued with a gallop, will avoid drinking at all. The most that should ever be done, is to suffer no horse to drink his fill at a river or pond; but having given him half what is necessary, walk him ten minutes, and then give him all that is required, and walk him again.

Sect. XV. Stabling and Grooming of Horses.

693. The stabling of horses is likewise a most important point in their management, the more so as being wholly a deviation from nature; hence, under the most judicious management, it is liable to produce some departure from health; and as sometimes managed, is most hurtful to it. Clothing, dressing, or exercising, are, as almost all horsemen say, also hurtful to the animals. 694. Every stable should be large, cool, and airy. It is too common to suppose that warmth is so congenial to horses, that they cannot be kept too hot; but there is reason to suppose that many of the diseases of horses are attributable to the overrating effects of unnatural heat, and of an air breathed and rebreathed over again. Blame is, in a great degree, responsible to reason and experience, to expect to keep animals, that from stables heated to sixty degrees, and further protected by warm clothing, are first stripped, and then at once exposed to a temperature at the freezing point? If it be argued that habit and exercise render these less hurtful, it will be easy to answer that their original hardihood is lost by confinement and artificial treatment; and that neither does exercise always tend to obviate the effects of this sudden change: for our best carriage horses, and hackneys also, have often to wait hours in roads and streets the exposure of which to the rays of the sun is more, or less, according to the measure of the sun. 695. The heat of a stable should be regulated by a thermometer, and the heat shown by it should never exceed 60° Fahrenheit in winter, or 65° or 63° in summer. To renew the air, the stable should be well ventilated; and which is best done by trunks or passages passing from the ceiling through the roof. It should not only be ventilated, but it should be so constructed as to admit light and air, without producing a current of wind on the bodies of the horses. Darkened stables are very hurtful to the eyes; neither do they, as was formerly supposed at Newmarket, to contribute to the digestion or rest of a horse.

696. A stable should have a close ceiling to keep the dust and dirt from the hay-loft from entering the horses' eyes. It is also necessary to prevent the ammonia gases from ascending and lodging in the stable. It is preferable that the hay-loft be altogether removed from over the stable; and if a very high ceiling is given to the room, the benefit of the air should be for the horses.

697. The form of the rack and manger should be attended to. Sloping racks are disadvantageous, as encouraging dust in the eyes. They should therefore be upright, and by no means so high as they usually are. The neck and head are sometimes injured by the stretch. As a proof that this is unpleasant to horses, many of them, first pull out all the hay, and then lie down easy. The manger should be sloping; the bottom, and of a proper height: care should be taken that no splinters are present to endanger the lips, nose, and mouth. The halter reins should, in good stables, be suffered to run within a groove in the rack and manger, to prevent the risk of splintering the rack by the practice in some stables of stuffed in the stalls to prevent dust, stage-wagon, and other hard-worked horses, to abandon hay-rafts altogether; but the hay being placed on the floor before the horses encourages him to lie down and eat it; by which much rest is afforded to the weak limbs, and much improvement in the eyes. The pungency of this effluvia is familiar to every one on entering a close stable in the morning, and when the long-soiled litter is removed, it is absolutely unbearable.

698. The litter of horses should be kept dry and sweet, and should be often removed. When it is still enough to remain, under the notion of making litter better dry; neither does the manure benefit as is supposed; for when it is removed to the dung pit, the close confinement does it more good than the open exposure in the stable, when it parts with its salts, on which its properties as manure partly end.

699. Horses should not stand on litter during the day, although very generally suffered to do so. Litter is thought to save the shoes and even the feet, by preventing the uneven surface of the stable from hurting them; but no litter holds the urine; it injuries the feet; and is very apt to encourage swelling at the hoofs: as we know by removing it, when horses immediately subjected to the clean dry pool without doors, which should be closed up, that a current of air may not come through the grating. Such a contrivance will effectively carry off the water, and prevent the volatile alkalii of the urine from imperceptibly warming the air around. For the same reason, it is advisable to make the mangers without the stable as soon as dropped; for the exhalations from that are also ammonia, and consequently hurtful. To this cause alone we may attribute many diseases, particularly the great tendency that is with the right side to his left, and carry him all under his belly to his chest, and so all over very well, from the knees and shoulders upwards: after that, go to the far side, and do in like manner. Then take a dead horse's tail, or a dusting-cloth of cotton, and strike that dust away which the curry-comb has
raised. Then take a round brush, made of bristles, and dress him all over, both head, body, and legs, to the very fetlocks, always cleansing the brush from that dust which it gathers, by rubbing it upon the curry-comb. After that, take a hair-cloth, and rub him again all over very hard, both to take away the loose hairs, and to help to lay his coat; then wash your hands in fair water, and rub him all over with wet hands, as well head as body; for that will cleanse all those hairs and dust the hair-cloth left. Lastly, take a clean cloth, and rub him all over till he be very dry, for that will make both coats a little less. Then take another hair-cloth for you should have two, one for his body and another for his legs), and rub all his legs exceedingly well, from the knees and hocks downwards to his very hoof, picking and dressing them very carefully about the fetlocks from gravel and dust, which will lie in the bending of his joints.

6709. The curry-comb should not be too sharp, or, at least, not used in a rude and severe manner, so as to bruise the skin, its delight and gratification. Thus, the great delight is too often the fate of thin-skinned horses to suffer much from the brutality of heavy-handed and ignorant farriers who do not recollect that the unhappy animal is suffering, every time he writhe and attempts to escape from the comb or brush, the same tortures that they themselves experience when tickled on the soles of their feet.

6710. The care of the legs and feet forms a most important branch of stable discipline. The legs must be kept perfectly dry and clean. Dirt suffered to form a lodgment, or wet remaining upon the legs in cold weather, especially in the splints, grease, manes, heels, and selvedges of the coronet, chincap, and such a train of stable plagues, as may baffle the most vigorous efforts during a whole winter. If any disposition to swellings, cracks, &c. make their appearance on the legs, particularly in winter, moderate bandaging, which every good groom knows how to perform, will contribute to the evil; if it, however, increase, have recourse to the veterinary directions. It forms a part of the constant attention of a good horse-keeper to see that the feet of his horses be well cleansed beneath the shoe with the pickler from all small stones or gravel, at every return from abroad. The shoes must be examined, that their ends do not press upon the crust, and that the nails be fast, and that the clinches do not rise to cut the horse. In these cases, instant application must be made to the farrier: horses ought by no means to remain in old shoes until the toe is worn away, or the webs become so thin that there is danger of their breaking, unless in case of brittle horses, when it is an object to shoe as seldom as possible. Upon the average, these are the nether nears, in general, a useful to take away the necessary when the best iron is made use of. Where any tendency to crry houts exists, the feet should be stopped with equal parts of clay, cow-dung, and chamomile every night; otherwise, twice or three times a week. When the natures are made by adjaing to the back of the little toe to the back of the outer one. It is also prudent, when the houts have any tendency to hardness and contraction, to water the fore part of the stall a little; and also occasionally, or constantly, to hang about the houts an apparatus, made by adding a circle of woolen cloth over a tape, which should be tied around the fetlocks loosely: the two: &c. It is also expedient, when the foot becomes dry, and correspondingly the horse is in a state of distemper, to keep him constantly in water, and will be found very convenient in keeping the feet moist and cool. Very brittle horses are greatly benefited by brushing them over with a mixture of whole oil and turpentine. It is considered as beneficial in all cases, to work them, and to keep them in good humor, who do no work, and to substitute tips; the growth of the crust and the enlargement of the heels being thereby promoted.

6711. The care of the furniture and trappings is another part of the duty of a horse-keeper. These are best kept in order by being instantly rubbed clean after use, and placed in a dry situation; by which method, neither oil nor scouring-paper is often found necessary. Great care should be taken to dry the pads of the saddles after journeys, and never to put a hardend and damp saddle upon the horse's back. The body-cloths are to be taken with the saddling of the saddle-cloths. The body-cloths are always kept perfectly soft, and free from dirt and sweat; and, after use, should be dried either in the sun or by the fire, and hung in a dry place: the body-cloths also should be washed much oftener than they generally are, and wound about them perfectly dry, and to be changed when they do no work, and to substitute tips; the growth of the crust and the enlargement of the heels being thereby promoted.

6712. The exercise of horses is essentially necessary for their health, as it counteracts the effects of the artificial life we force on them. High feeding, heated stables, and unnatural clothing are, particularly the first, counteracted by proper exercise; and without it, horses become passive, fat, heavy, and greased; for, when the secretions do not find themselves natural vents by perspiration, &c., they will find themselves artificial ones. Exercise keeps down the fat, and it also hardens and condenses the muscles by drawing their fibers nearer together; it likewise enlarges the muscles. Thus the appearance, as well as the strength of the horse, is increased by the frequent exercise in cold weather, or the occasional exercise of one of them in cold weather by fat, &c. Exercise increases the wind by taking up the useless fat, and by accumulating the lungs to expand themselves.

6713. The quantity of exercise necessary for a horse must be regulated by a variety of circumstances; as age, constitution, temper, and his work. A young horse requires more exercise than an old one, but it should be neither very long, nor very fattiging. Some colts are observed to come out of the breeder's hands with splints and spavins, owing to the severe exercise they have undergone. When horses are put to work, it is not to be done too soon in the morning, if the weather is cold; nor to be done when the weather is very cold, as all that is necessary: but, on days when their common work is not expected to occur, a full-fed horse should be exercised twice a day, an hour at each time; or, if only once a day, then an hour and a half or two hours' exercise should be given; two thirds of which ought to be passed in walking; the other should be passed in a moderate trot in the hackney, and divided into galloping and trotting in the hunter. The racers has his regular gallops at stated periods; but the exercise of each should always finish with a walk of sufficient length, to bring the horse in cool, both in person and temper.

SECT. XVI. Management and Working of Horses.

6714. The working of horses includes the racing, hunting, and journeying of saddle horses; and the treatment in harness of coach, wagon, cart and farm horses.

SUBSECT. I. Management and Working of Race Horses.

6715. In the managing and working of race horses, three things are to be considered, the preparation of the horse, the conduct of the rider, and the after-treatment of the horse. The preparation of a race horse for the work consists in careful depend on the horse's muscles in training, by proper food and exercise, and to refine his wind, by clearing his body to that degree of perfection that is attainable by art. It is first necessary to ascertain correctly the present state of the horse, as whether he be low or high in flesh; and in other cases a proper estimate should be formed of the time and means required to bring him to true running condition.

6716. If a race horse be low in flesh, it is necessary to judge of the cause of such state, and to act according to the preceding reasoning, and to direct the proceeding of the treatment of each case. (657b.) It is to be remarked, that horses are less to be depended on for this purpose than generous food, as malt mash; and if any thing of the kind be used, let it be the simple barley. (657b.) Feed frequently, and by little at a time; while he is thus low, let his exercise be walking only, and by no means

spare his water, or he will become hide and evan; every time he watch him, that till feeding may not disagree
by making his heels swell, or his coat unrthightly; and if such appearances occur, mash him, and begin his scourings, otherwise abstain from physicking until he is in better health. As he improves in condition, increase the work, but not too much; and when his coat is dry and hard, give him an oats and beans, with wheaten or barley bread; the beans and oats are to be put into a bag, and beaten till the hulls are all off, and then winnowed clean; and the bread, instead of being chipped in the common way, is to be rubbed and the crust clean off.

671. If the horse be in good flesh and spirits when taken up for his morning's preparation, cordials are altogether unnecessary; and the chief business will be to give him good food, and so much exercise as will keep him in wind, without over-sweating or fatigueing him. If he takes larger exercise after dinner, you may allow him half a pint of water, or a dram of spirits, if necessary. The exercise for the race, and the food given him, will be intimately connected with the result. This will put him upon his mettle, and the beating them will give him spirits. This, however, is to be cautiously observed, that he has not an injurious, or in the language of jockeys, a bloody heat given him for ten days or a fortnight before the race is to be run for; and that the last heat that is given him the day before the race must be in his clothes: this will make him run with greatly more vigour when stripped for the race, and feeling the cold wind on every part. In the second week, the horse should have the same food and more exercise; and in the last fortnight he must have dry oats, that have been hulled by the mill, and jockeys wear the same sorts of clothes, and give him comparatively dry; and when as dry as before, is to have them: this sort of food being considered by them as very light of digestion, and very good for the creature's wind. The beans in this time should be given much and frequently, and the bread partly or wholly made of the same, and the oats and barley in equal parts. If he should become costive under this course, he must then have bran-water to drink, or some ale and white's beaten together; and keep his body moist. In the last week all mashing is to be omitted, and barley-water given him in its place, and every day, till the day before the race, should have his ill of hay; then he must have it given him more, or, if he may have time to digest it; and in the morning of the race-day, must have a toast or two of white bread soaked in ale, and the same just before he is led out of the field. This is an excellent method, because the two extremes of fulness and fasting are at this time to be equally avoided; the one affecting his wind, and the other occasioning a faintness that may make him lose. After he has had his food, the litter is to be shook up, and the stable kept quiet, that he may be disturbed by nothing till he is taken out to run.

672. As the habit of a rider for giving a horse a swift pull, it is necessary, in the art of riding a race, to have that one that is not only expert and able, but honest. He must have a very close seat, his knees being turned close to the saddle skirts, and held firmly there; and the toes turned inwards, so that the spurs may be turned outward to the horse's belly; his left hand governing the horse's mouth, and his tigh the whip. During the war of the legs in the horse, he must ride light to sit the stirrups. Some jockeys fancy the last a becoming seat; but it is certain, that all motions of this kind do really incumbrate the horse. In spurring the horse, it is not to be done by sticking the calves of the legs either in, or to press them outwards, but, on the contrary, the toes are to be turned a little outwards, that the heels being brought in, the spurs may just lie one upon the other, to touch the sides. A sharp touch of this kind will be of more service toward the quickening of the pace, and will sooner draw blood than one of the common coarse kicks. The expert jockey will never spit, but is always so disposed as to press the toes to sit in the stirrup; but, on the contrary, those between the shoulders and the girt; this is the tenderest part of a horse, and a touch there is to be reserved for the greatest extremity.

673. In unshippding the horse, it ought always to be done over the shoulder, on the near side, except in very hard running, and on the point of victory; then the horse is to be struck on the flank with a strong jerk; for the skin is the most tender of all there, and most sensible of the lash. When a horse is whipped and spurred, and is at the top of his speed, if he claps his ears in his pole, or whisk his tail, it is a certain sign that he is tired, or his sides hurtful; and the master, or jockey, has no business between the shoulders and the girt; this is the tenderest part of a horse, and a touch there is to be reserved for the greatest extremity.

674. When running on good smooth ground, the jockey is to beat his horse as much as the adversary will give him room for it; so long as the horse is of a fiery disposition, the jockey is to either run just behind him, or check by jule with him, making a noise with the whip, and by that means forcing him on faster than his rider would have him, and consequently, spending him so much the sooner; or else keep him just before him, in such a slow gallop, that he may either overreach, or by treading on the heels of the fore-horse, endanger tumbling over. Whatever be the ground that the adversary's horse runs worst on, the cunning jockey is to ride the most violently over; and by this means it will often happen, that in following he either stumbles or claps on the back sinew. This makes the horses of the hand turn the spur, and the swift pull on their sides, in what manner he makes use of them: and when it is perceived by any of the symptoms of holding down the ears, or whisking the tail, or stretching out the nose like a pig, that the horse is almost blown, the master, or the jockey, will keep him on to the speed, and he will be soon thrown out or distressed. If the horse of the opponent looks dull, it is a sign his strength fails him; and if his flanks beat much, it is a sign that his wind begins to fail him, and his strength will soon do so too.

675. The after-management of a horse who has run includes the treatment between the heats, and the treatment after the race is over. First, for a pinch, oretter, every licot, and dried hay, both linen and woolen, ready to run him down all over, after taking off the sweat with what is called a sweet-knife; that is, a piece of an old sword-blade, or some such thing. After the horse has been well rubbed all over, the whole being wetted in common water, till the time of starting again. When it is certainly known that the horse is good at the bottom, he must be rid every heat to the best of his performance; and the jockey is as much as possible to avoid riding at any time of the horse, or standing, or stopping, but to ride out the whole heat with the best speed he can. If, on the contrary, he has a fiery horse to ride, and on which he cannot be held, he is to be started behind the rest of the horses with all imaginable coddness and gentleness; and when he begins to ride at some command, then the jockey is to put up to the other horses; and if they ride hard, and are hard pressed, the draughts are to be done away; if the horse begins to rack hot, and they want a sob, the business is to keep them up to that speed; and when they are all come within three quarters of a mile of the post, then the time is to push for it, and use the utmost strength of the creature's power.

676. When the race is over, the horse is immediately to be clothed up and rode home; and immediately
on his coming into the stable, the following drink is to be given him: — Beat up the yokes of three eggs, and put them into a pint and a half of sound ale, made warm; and let it be given with a horn. After this, he is to be rubbed well down, and the saddle-place rubbed over with warm water and vinegar, and the places where he has trodden on his head be thoroughly washed. After this he should have a feed of rye bread, then a good mash, and at some time after these as much hay and oats as he will eat. His legs, after this, should be bathed some time with a mixture of vinegar and water.

6725. The managing and working of the hunter includes his preparation for hunting, his condition, and his treatment for the prevention of the diseases which take place during the hunting season. Next, the preparation of the hunter must, like that of the race horse, be commenced by an estimation of his state and condition. If taken fresh from grass, it should be in due time: first, that he may be well prepared for the grass and its manner of growth not much used in the heat of summer. A still better method is to continue to let him run out in the day and graze, having a shed to house himself from heat and rain. He is also to be fed and exercised, nearly as in the common training, for hunting condition. In this, he should be table-bound, or surfed, and he will prove infinitely easier hard by afterwards. It is even the practice with some of the best sportsmen to allow their horses to run out all the hunting season, unless the weather be very severe; when they are only stabled in a loose place. They are allowed as much corn as they can eat, and are found, if a little rougher in their coats, infinitely superior in hardiness, and exemption from the dangers of cold.

6726. A hunter taken from grass or in very low case should be treated as already fully detailed under condition. (644.) Great care must be taken that all the alterations in heat of stable, clothing, feeding, &c., are gradually brought about; by which means his flesh will be gradually expanded, and his first walking exercise, and increasing it as he advances in flesh and strength, his wind also will become excellent.

6727. In the physicking of hunters, particularly when they are low in flesh, much caution is requisite that it be not over-done. It is the practice with some, and by no means a bad one, to give no physic; but to give more time in the preparation. Others, again, give mild grass physic, which is an excellent plan, when the weather is fine. (See Physicking, 644.)

6728. The nourishment of a hunter and not from grass depends principally on regular exercise, and the best hard food; physicking him or not, according as he may be suspected to be foul, or as his wind may seem to want mending; but above all, whatever is done, should be done regularly; and his exercise should be rather long continued than the violent. Oats with the proper hard food for hunting cases will not be contemptuous the bowels; which must be oiled by bran mixed with the other food, if such should be the case. Bread is not necessary, but for tender delicate horses; but every thing should be of the best.

6729. They drive before a horse to have him in condition to treat him somewhat differently, but this is seldom necessary. It is evident he should be well fed, and that not late at night, that he may lie down early. Some feed in the morning, which others avoid; but when it is considered, as has been fully explained (644.) how ill all preparations will be at once seen, that if very early by five or six o'clock he could be fed with a moderate quantity of corn wetted, it would tend to support him through the day.

6730. On the return of a horse from hunting, the care bestowed on him should be extreme; as it depends on the immediate recovery of his strength. If he has fished very long, and particularly if he be disinclined to eat of himself, horn down a pint of ale, with two pints of thick gruel. No prudent sportsman will bring in a horse hot; but if unavoidable accidents prevent this caution, let the horse be again led, and have the latter part of the day过得 in his clothes when afterwards. Encourage him to state as quickly as possible, after which proceed to hand-rub him all over carefully, placing before him a little of the best hay well sprinkled with water. If he refuse this, offer him three quarters of very clean chilled water. When perfectly clean, let the horse be carefully sitched, all staples not having pierced them, or that his shoes have not been forced away by over-reaching, or by the suction of clayey ground; or that thorns be not lodged in his knees, hocks, and sinews. After all these matters have been well attended to, remove him from his stall to a loose box, well hedged up. A loose box is useful also his stall, in order to prevent the swelling of the legs, and is better than bandaging when it can be avoided, which gives a disinclination to lie down. If the horse be off his food the next day, give him a corrials ball (Vet. Pharm. 658.) and a malt wash, and afterwards a few cut carrots, which will assist to bring him round more speedily.

Subsect. 3. Working and Management of Riding Horses.

6732. The working and manning of hackney or rating horses include what is required for them as pleasure horses for ordinary airings; and what they require when used for purposes of travelling or long journeys. It embraces also their stable management in general, with the proper care of horse and stable appointments; all which are usually entrusted to a servant, popularly called to transfer this; or if he be not in the best condition. The distance a horse can perform with ease depends greatly on circumstances.

3 T
Light careassed horses, very young ones, and such as are low in flesh, require often baiting, particularly in hot weather; horses in full condition, above their work, and well careassed, and such as are from seven to ten or twelve years old, are better when ridden a distance of fifteen or twenty miles, with a proportionate length of baiting time afterwards, than when baited one or two days before the ride. In hot weather, let the horse have two or three good clean sips, but no more, of water or milk; and if he tends to prevent excessive fatigue, occasionally walk yourself up and down, which greatly relieves him, and at such time remove the saddle, by shifting which, only half an inch, you greatly relieve him; and during this time, perhaps he may stale, which also is very refreshing to him. It may be as well, in a dirty country, to take this opportunity of examining that no stones are got into the feet likewise.

6731. When a horse is brought into an inn from his journey, if he be very hot, first let him be allowed time to stale; let his saddle be taken off, and with a sweat knife draw the perspiration away; then, with a rug thrown round him, let him be led out and walked in some sheltered work; and when he will not afterwards break out into a secondary and hurtful sweat; but by no means let an idle ostler hang him to dry without the stable. Being now dried, remove him to the stable, where let some good hay, sprinkled with water, be placed before him; if very thirsty, give three or four quarts of washed water, and let him be thoroughly dressed, hand-rubbed, foot-packed, and foot-washed; but by no means let him be ridden into water; or, if this practice is customary, and cannot be avoided, let it be not higher than the knees, and afterwards insist on the legs being rubbed perfectly dry; but good hand-rubbing and light spouging is better than washing. Having thus made him comfortable, procure to feed him with corn and beans according as he is used.

6732. To feed a horse when very hard ridden, or if weakly and tender, it is often found useful to give bread, or bread with ale: if this be also refused, horn down oatmeal and ale, or porridge; but the more consequence, if the weather is to be of several days' continuance, or if it is to consist of a great distance in one or two days, that the baitings are sufficiently long to allow the horse to digest his food; digestion does not begin in less than an hour, and is not completed in less than three; consequently any horse that is not to be used less than two hours after has a right object of his object on his former strength, and therefore it cannot continue. After a horse is fed he will sometimes lie down; by all means encourage this, and if he is used to do it, get him a retired corner stall for the purpose.

6733. The night baiting of a journeying horse should embrace all the foregoing particulars, with the addition of foot stopping; and care that his stable be of the usual temperature to that to which he is accustomed; and no wind or rain can come to him. Give him now a full supply of water: if he has been kept exposed to cold, procure him a warm bed; or if his dung be hardened, give him a little proportion of oats and beans be his supper, with hay, not to blow on half the night, but enough only to afford nourishment.

6740. When returned home from a journey, if it has been a severe one, let the horse have his fore shoes taken off, and, if possible, remove him to a loose box, with plenty of litter; but if the stones be rough, or the pavement uneven, put on tops, or merely loosen the nails of those shoes he has on; keep the feet continually moist by a wet cloth, and stop them at night if the shoes be left on; mash him regularly, if very much fatigued, or reduced, let him have a good feed in an hour or two in the middle of the day to grace: bleeding or physicking are unnecessary, unless the horse shows signs of fear. If the legs be inclined to swell, bathe them with vinegar and chamberlyne, and bandage them up during the day, but not at night, and the horse will soon recover to his former state.

6741. In working and managing horses in curricles, two-wheeled chaises, and similar cases, great feeling and nicety is required, not to overload or overdrive the animal; to see that the weight is duly proportioned between the wheels and horse's back, and that the harness does not pinch; but precautions on this head can be of much use, unless the driver be a humane and considerate person, and one who sets very just value on the services of the noble animal committed to him. In Russia, the drivers of two-wheeled carriages, as droshkeys, sledges, and others, corresponding to our gigs and barouche, have a barbarous custom of teaching the horses to turn round their heads, the one to the left, and the other to the right (Fig. 850), the sight of which is very offensive to a stranger.

SUBSECT. 5. Working of Cart, Waggon, and Farm Horses.

6742. In working and managing coach horses, the same attention to grooming in all its departments is required as for saddle horses. Coach horses should never be brought into full work before they are five years old, and when well fed on hard food, they may be worked at an average of thirty miles per day. Their principal meals should be in the morning and after their work is over for the day, as the action of trotting fast materially impedes digestion.

6743. In working and managing cart and waggon horses, a similar attention is requisite as for coach horses, though perhaps in a somewhat lesser degree, the animal being harder.

6744. The working and managing of farm horses includes the age at which they are put to work, the quantity of work they should perform, and their feeding and general management. It is the opinion of most horse-keepers, in the labourer's art, that horses are to be fed in full use usually when four or five years old, according to the nature of the soil, and the numbers of the team; but they are always understood to be able to pay for their maintenance after they are three years old, by occasional work in ploughing over the stock; and it thinks it probable they might be put to work at four years old, were the same attention paid to their breeding and rearing that is paid to cattle in a dairy. The work which a farm horse ought to perform is evidently a question of circumstances, which does not admit of any precise solution; a two-horse plough may, on an average, work about an English acre a day throughout the year; and, in general, according to the nature of the soil, and the labour that has been previously bestowed on it, a pair of horses, in ploughing, may travel daily from ten to fifteen a
miles, overcoming a degree of resistance equal to from four to ten hundred weight. On a well made road, the same horses will draw about a ton in a two-wheeled cart for twenty or twenty-five miles every day; and one of the better sort, in the slow movement of the carrier or waggoner, commonly draws that weight. In some places horses pull in the Yorkshire manner, in the day permits, nine hours, and in others ten hours a day; but for three or four months in winter, only from five to eight hours. In the former season they are allowed to feed and rest two hours from midday, and in the latter they have a little corn on the field, when working as long as there is day light, but none if they have not worked six hours. *Viz. Art. 45.*

*644.* The feeding of farm horses is a subject of great agricultural importance, and has excited considerable discussion among speculative agriculturists, who have generally urged the great expenses attending it, and the loss resulting from the same. Others, with a less amount of experience, have been of opinion, not that the animals should be starved, but that either will be able to perform their work under such treatment, as well as if they were properly nourished, is contrary to reason and experience. It is observed by the judicious writer so often quoted, that horses can never perform their labour, according to the present courses of husbandry, on carrots, turnips, or grass, and chieftly on feed. They are in the best possible manner nourished and dressed, but they will work as much more, and thrive as much better, with oats or beans in addition, as fully to repay the difference in expense. One of the three meals a day, which farm horses usually receive, may consist of roots; and a few of them, every twenty-four hours, are highly conducive to the health of the animals: but we have never had occasion to see any horse work regularly throughout the year, in the way they are usually worked in the best cultivated districts, without an allowance of at least an English peck of oats, or mixed oats and beans, daily, less or more at particular periods, but rather more than this quantity for at least nine months in the year.

648. Brown does not approve of giving much grain to young horses, thinking it expensive, and not so conducive to their health as when they are supported on green food. In the winter and spring, a few months of winter, and a few months of summer, by keeping their blood in good order, swelling their bone, and hastening their growth. A plentiful supply of grass in summer ought always to be allowed, as their condition through the winter depends greatly upon that circumstance. It is an object deserving of attention, that flesh once gained ought never to be lost. It is true, that every horse whatever his age, and whatever is his state of accommodation, is suffered to take a retrograde course, which afterwards must be made up by extra feeding, or a loss be sustained, in a direct proportion to the degree of retrogradation that has actually occurred.

653. The keenness of a farmer's working cattle, and their reluctant movements, clearly mark his unprosperous condition. There are particular operations, indeed, such as turnip-sowing, seeding, sowing, harvest-work, &c., which require to be executed with so great despatch in our variable climate, that universal attention, and the greatest care, is absolutely necessary, not only to prevent the animals from losing flesh, sometimes even when their spirit and vigour are not perceptibly impaired. Such labours, however, do not continue long, and should always be followed by a corresponding period of indulgence. It is particularly dangerous and unprofitable to begin the hard treatment during winter, and spring, or any other season, under such circumstances. It is not necessary even to mention the cases of horses suffering from scurf, or the leg troubles, or the liberal use of the brush and the curry-comb; for it would be an impossible thing to happen in any one manure, and when the animal is out of order, any remedy lies in physic, once or twice a year; either the regular aloetic dose, or salts given in pails of warm water, or sulphur and cream of tartar; one third of the latter mixed in the corn. All horses kept in the stall become, more or less, internally loaded; and it is an error to suppose cart-horses are not equally benefited with others by purging physic.

651. The cleaning and dressing of farm horses was formerly very little attended to; but at present its importance to the health of the animal is better understood. Donaldburn recommends that the heels, legs, head of the knee, and hock, the breast under the flanks; in short, all parts out of sight, of cart horses, whilst standing in the house, should be kept perfectly free from dirt and scurf, and the skin supple; the parts more in sight will take care of themselves. In a deep country, it is much the better practice, notwithstanding the prejudice to the contrary, to trim their legs and coat by themselves, and when they have worn all the wool, to have them shorn over, or to have the same done by those who are experienced in it. It is not necessary to mention the cases of the coat, in which the liberal use of the brush and the curry comb twice a day; frequent but moderate meals, consisting of a due proportion of succulent joined to more solid food; abundance of fresh litter, and great attention to method and cleanliness, are as indispensable in this as in all other parts of the economy, as the proportion of solid to fluid food should be held to be in the treatment of horses kept for pleasure. Good dressing, with all well informed and attentive men, is considered to be no less necessary to the thriving of the horses than good feeding; according to a common expression, it is equal to half good food.

652. The general management of horses in the improved districts of the north may be presented as a good example. There, for about four months in summer, horses are fed on pastures; or on clover and rye-grass, and tares cut green, and brought home to the stable or fold-yard; the latter method being by far the most economical and advantageous. For the other eight months, they are kept on the straw by oats, beans, and peas, and on clover and rye-grass hay. As soon as the grass fails towards the end of autumn, they have hay for a few weeks, and when the days become so short as to allow of no more than from six to eight hours work, they are very generally fed with different kinds of straw, according to the circumstances of the farm; in the month of March they are again put to hay till the grass is ready for being cut. Throughout all the year they are allowed more or less corn, when constantly worked; and during the time they are on dry fodder, particularly when on straw, they have potatoes, yams, or Swedish turnips, or any other coarse roots, in a few instances, and even barley, or barley straw. A pound of all these roots is of great importance to the health of horses, when succulent herbage is first exchanged for hay at the end of autumn; and it is no less so towards the latter end of spring, when hay has become sapless, and the horses are usually retired. At these two periods, therefore, it is the practice of all careful horsemen to give an ample allowance of some of these roots, even though they should be withheld for a few weeks during the intermediate period.

653. The quantity of these different articles of food must depend on the size of the horses, and the labours which they perform; and the value upon the prices of different seasons, and, in every season, on the situation of the farm with respect to markets, particularly for hay and oats, which bring a very different price near large towns, and at a few miles distant. It is for these reasons that the yearly expense of a horse is so variable. From the first to the last of every sum, from the last to the first, it is usual to attend to the expense of feeding horses that are capable of performing the labour required of them, under the most correct and spirited management. Such horses are fed with oats, sometimes with beans, three times a day, for about eight months; and twice a day for the other four, when at grass; and, at the rate of two bushels of oats to every half quarter of oats, or twenty bushels Linlithgow measure in the year. When on hay, he will require about one stone of twenty-two pounds avoirdupois daily, and five pounds more if he does not get roots. One English acre of clover and rye-grass, and tares, may be reckoned as equaling an acre of potatoes, or an acre and a half of oats, or two of beans, or six of turnips, or ten of turnips, or twenty of common grass. In the eight months he is fed with hay or straw. The use of these roots may admit of a small diminution of the quantity of corn in the winter months, or a part of it may be, as it almost always is, of an inferior quality.
The expense of feeding a horse throughout the year may therefore be estimated, in regard to quantity, as follows: —

Oats, fifteen quarters.

Timothy, clover, Timothy, and rape-seeds, and tuber.

Hay part of October and November, March, April, and May, 1 ton.

The expense of land required for a horse’s maintenance, supposing the soil to be of a medium quality, may be about five acres; that is, for oats three acres, soiling one, and one more for hay and roots. On rich soils four acres will be sufficient; but on poor soils, and wherever horses are kept at pasture, the produce of six acres and a half, or seven acres, will be consumed and all losses balanced, when worked on the parterre. The straw of about two acres must be allowed for fodder and litter, the last of which has not been stated above; because, at a distance from towns, what is allowed for litter must, at any rate, be converted into dung. If sixty acres, therefore, should be assumed as the average extent of land that may be kept in cultivation by two horses, according to the produce of ten acres of this will be required for their maintenance; or, a horse consumes the produce of one acre out of every six which he cultivates, according to a four or six years’ course, and something more than one acre out of every five which he ploughs annually. (General Report of Scotland, vol. iii, p. 192.)

Chap. II.

The Ass.—Equus Asinus L. Ace, Fr.; Ass, Ger.; Asno, Span.; and Asino, Ital.

6755. The excellencies and defects of the common ass have amply engaged the lively pens of several descriptive writers on the history of animals; and of none with more happy effect than those of the eloquent Buffon, and the ingenious Albre de Pluche. The nature of the ass is hasty, and quiet, and bears correction with firmness. He is extremely hardy, both with regard to the quantity and quality of his food, contenting himself with the most harsh and disagreeable herbs, which other animals will scarcely touch. In the choice of water he is, however, very nice; drinking only of that which is perfectly clear, and at brooks with which he is acquainted. He is very serviceable to many persons who are not able to buy or keep horses; especially where they live near heaths or commons, the barrenest of which will keep him; being contented with any kind of coarse herbage, such as dry leaves, stalks, thistles, briers, chaff, and any sort of straw. He requires very little looking after, and sustains labour beyond most others. He is seldom or never sick; and endures hunger and thirst longer than most other kinds of animals. The ass may be made use of in husbandry to plough light lands, to carry burdens, to draw in mills, to fetch water, cut chaff, or any other similar purposes. The female (fig. 581) is also useful in many cases for the milk which is excellent; and she is be of more advantage to the farmer if used, as in foreign countries, for the breeding of mules. The skin of the ass is extremely hard, and very elastic, and is used for various purposes; such as to cover drums, make shoes, or parchment. It is of the skin of this animal that the Oriental make the taff, or, as we call it, shagreen. The milk of the ass is the lightest of all milks, and is recommended by medical men to persons of delicate stomachs; the flesh, and the hair of the tail and mane, are used as those of the horse.

6758. The ass attains his full growth in three or four years, and may then be put to work. Like the horse, he will live to 25 or 30 years: it is said the female lives longer than the male; but, perhaps, this happens from their being often pregnant, and at those times having some care taken of them, instead of which the males are constantly worn out with fatigue and blows. They sleep less than the horse, and do not lie down to sleep, except when they are exceedingly tired. The male ass also lasts much longer than the stallion; the older he is, the more ardent he appears; and, in general, the health of the animal is much better than that of the horse; he is less delicate, and not nearly so subject to maladies. Ophthalmal, Contraction of the feet also is very seldom observed in him.

6759. The different breeds or races of the ass are much less known than those of the horse; because in this country they have not been taken the same care of, or followed with the same attention. Travellers of which, being slow and heavy, is used for burden; one other is kept like a cart horse, for heavy sandle. The latter have smooth hair, carry their heads well, and are much quicker in their motion; but when they ride them they sit better than the horse, and are the more room for breathing. According to Dr. Russell, there are two sorts in Syria, one of which is like ours, and the other very large, with remarkably long ears, and both kinds are employed for the purpose of carrying burdens and solemn trains, (fig. 582.)
7670. In breeding from the ass, the same general rules should be attended to as in the horse breeding. The male ass will procreate at the age of two and a half years, and the female still earlier. The stallion ass should be chosen from the largest and strongest of its species; he must at least be three years old, but should not exceed ten; his legs should be long, his body plump, head long and light, eyes brisk, nostrils and chest large, neck long, loin fleshy, ribs broad, rump flat, tail short, hair shining, soft to the touch, and of a deep grey. Those are reckoned the best shaped that are well squared, have large eyes, wide nostrils, long necks, broad breasts, high shoulders, a great back, short tail, the hair sleek, and of a blackish colour.

7671. The best time for covering is from the latter end of May to the beginning of June, nor must the female be hard for covering whilst with foal, for fear of casting; but the more the male is worked, in moderation, the better he will thrive. She brings forth her foal in about a twelvemonth, but, to preserve a good degree of flesh, she should be covered two in two years, and working to be twice between the months of March and June. The best age to breed at is from three years old to ten. When the foal is cast, it is proper to let it run a year with the dam, and then wean it by tying up and giving it grass, and some barley or oats. If and, when it has filled the test, it should be turned out into a pasture; but if it be in winter, it must then be fed at times, till it be able to shift for itself.

7672. The ass may be broken and trained at the end of the second year; but should not be worked sooner than the third year. Breaking is easily effected when two years old, or it may be let alone still longer, as till three years old. It is easily done by having small weights on his back, and increasing them daily; then set a boy upon him, and so increase the weights as may be proper, till they are sufficiently heavy.

7673. The age of the ass is known by his teeth in the same manner as the horse. At two years and a half he has four, but from the sixth he must be out, and the other on each side soon follow; they are renewed at the same time, and in the same order.

7674. The anatomy and physiology of the ass do not differ from those of the horse essentially. The concha cartilages of the ears are, however, considerably more elongated; the spinous processes of the dorsal vertebrae forming the withers are less extensive; and the bones of the extremities in general are less angularly placed, from whence results his inferiority in speed. It is also to the unbinding lines of the spine, that his motions are rendered so uneasy to a person placed on the middle of his back. Some specially occur in his head, and when small and upright. His laryngeal sacs and cordes vocales are not altogether like those of the horse, from whence his aptitude to bray instead of neighing.

In the ass there are three laryngeal sacs as in the horse; but instead of a wide opening into them, there is a small round hole, and the interior sac is a real bag of considerableness. The horse has none. These organs in the ass are compound of these forms. Braying appears produced through the mouth, whereas neighing is principally effected by the nose. There is a hollow membranous cavity at the back of the mouth that is greatly assistant to this trumpet sound, which is effected by convulsively displacing the velum palatit by alternate inspirations and expirations.

7675. The diseases of the ass, as far as they are known, bear a general resemblance to those of the horse. As he is more or less in a state more approaching to natural, he has few diseases. Those few, however, are less attended to than they ought to be; and it is for the veterinary practitioner to extend to this useful and patient animal the benefit of his art, in common with those of other animals. The ass is seldom or never troubled with vermin, probably from the hardness of the foot, and with heels projecting beyond the heel of the foot, and slightly turned up, for he seldom overreaches; but much care is required in using small nails, and in very carefully driving them. The hinder shoes differ little from those used for the fore feet.

Chap. III.

The Mule and Hinny, Hybrids of the Horse and Ass.

7676. The mule (Equus Asinus var. 7 Maulus L. Grand Mulet Fr.; Grosser Maulwesel, Ger.; Mula, Span, and Ital.) is the hybrid produce of an ass with a mare, having a large clumsy head, long erect ears, a short mane, and a thin tail.

7677. The hinny (Equus Asinus, var. 8 Hininus L. Bardeau or Petit Mulet, Fr.; Kleiner Maulwesel, Ger.; Mulus, Span, and Ital.) is the hybrid produce between the she-ass and a stallion; the head long and thin, the ears are like those of a horse, the mane is short, and the tail is well filled with hair. The hinny is much less common than the mule; because, being less hardy and useful than the other, he is never cultivated.

7678. The mule, commonly so called, is much valued for the saddle, and for drawing carriages in Spain, Portugal, Italy, and the East, and in the warmer parts of America. In those countries where great attention is paid to the breed, it is as tall as the horse, exceedingly well limbed, but not so handsome, especially about the head and tail. These animals are mostly sterile; some, indeed, have thought that they are altogether incapable of producing their kind; but some few instances have occurred in which female mules have had foals, and in which even the male has impregnated females both of the ass and horse species, though such instances are exceedingly rare.

7679. The mules made use of in the southern parts of Europe are now brought to an astonishing perfection as well as great size. (fig. 832.) They are usually black, strong, well-limbed, and large, being mostly bred out of fine Spanish mares. They are sometimes fifteen or sixteen hands high, and the best of them worth forty or fifty pounds. No creatures are so proper for large burdens, than these horses, and are often as thickset as our dray-horses, and will travel several months together, with six or eight hundred weight upon their backs. Some think it surprising that these animals are not more propagated here, as they are so much harder and stronger than the horses bred the same place; and that general complaint made on the obscurity of their culture is, that these horses are stubborn; but this is owing to neglect in breeding them, for they are as gentle as horses in countries where they are bred with proper care.

7680. In the breeding of mares, mules that are of a very large breed and well made should be employed, though the young, full in life, large hindered, but small limbed, with a moderate-sized head, and a good forehand. It is found of advantage to have the foals from the time of their being dropped often

---

3 T 3
PRACTICE OF AGRICULTURE.

Part III.

handled, to make them gentle; it prevents their hurting themselves by skittishness and sudden frights; and they are much easier broken at the proper age, and become docile and harmless, having nothing of that viciousness which is so commonly complained of in these animals. They may be broken at three years old, but should never be permitted to do much hard work till four, as they are thus secured from being hurt by hard labour, till they have acquired strength enough to bear it without injury. An expert breeder of these animals found, that feeding them too well while young, was not only incurring a much larger expense than was any way necessary, but also made them wonderfully nice and delicate in their appetites ever after. He therefore contented himself with giving them food enough to prevent their losing flesh, and to keep up their growth without palling their appetites with delicacies, or making them over-fat: he also took care to defend them from the injuries of the weather by allowing them stable-room, and good litter to sleep on, besides causing them every day to be well rubbed down with a hard wisp of straw by an active groom. This was scarcely ever omitted, particularly in cold, raw, wet weather, when they were least inclined to exercise themselves. When three years old, mules are proper for use.

6772. The shoe for the mule is by some made not unlike the bar shoe before, and the common shoe behind; by some both fore and hind shoes are made to project considerably beyond the toe, under an idea of increasing the points of contact with the ground; but the most usual shoe is one formed between the usual horse and ass shoe.

CHAP. IV.

6773. The neat or horned cattle used in agriculture are included under two species of Bòs; the B. Taurus or ox, and the B. bòbulus or buffalo; the latter less used in Britain than on the Continent and in other countries. These animals are more universally used as beasts of draught and burden than the horse, and have the additional advantage of furnishing excellent food and other valuable products. There is scarcely a country in which the ox or the buffalo is not either indigenous, or naturalised and cultivated; while in many parts of the world the horse is either wanting, or reserved for the purposes of war or the saddle.

SECT. I. The Ox. — Bòs Taurus L.; Ochs, Ger.; Boeufs, Fr.; Buey, Span.; and Bue, Ital.

6774. The male ox is the bull (Taureau, Fr.; Stier, Ger.; Toro, Span. and Ital.) and the female the cow (Yache, Fr.; Kuh, Ger.; and Fiona, Span. and Ital.). The bull and cow inhabit various parts of the world, and, as already observed, are domesticated everywhere. In most countries, however, they are the mere creatures of soil and climate, the same attention in breeding and rearing that is bestowed on the horse being withheld; the natural habits little restrained or the form little improved for the purposes of milking, fattening, or for labour. It is almost exclusively in Britain that this race of animals has been ameliorated so as to present breeds for each of these purposes, far superior to what are to be found in any other country. Notwithstanding this, however, much certainly remains to be known regarding the nutrition afforded by different kinds of herbage and roots; the quantity of food consumed by different breeds, in proportion as well to their weight at the time, as to the ratio of their increase; and the propriety of employing large or small animals in any given circumstances. Even with regard to the degrees of improvement made by fattening cattle generally, from the consumption of a given weight of roots or herbage, no great accuracy is commonly attempted; machines for weighing the cattle themselves and their food, from time to time, not being yet in general use in any part of Britain. We shall consider this valuable family as to variety, criteria, breeding, earing, feeding, working, fattening, and milking: the manufacture of milk will be treated of in a succeeding chapter.

SUBSECT. I. Varieties and Breeds of the Bull.

6775. The varieties of the wild ox are the bonasus and the bison (fig. 112); the first with a long mane, and the last with a gibbous back. They inhabit the woods in Madagascar and many other countries of the East; and the bison is even said to be found in Poland.
VARIETIES

676. The varieties of the European cow, according to Aiton, are innumerable. The pliancy of their nature is such, that they have been formed into many diversities of shape, and various qualities have been given them, very different from the original stock. The *auro*, or cows of Lithuania, are almost as large as the elephant; while some of those on the Grampian hills are as small as the size of a goat; and cows are found of every diversity of size between the one and the other. They are not less varied in their shapes. The *bison*, which is a species of the cow family, and which readily propagates with our cows, wears a strong shaggy mane, like the lion; a beard, like the goat; a white hair under its neck and breast; a covers its four legs; a bump upon its shoulders, nearly as large as that worn by the camel; sometimes forty or fifty pounds in weight), with a tail that scarcely reaches the top of its buttock; and it resembles the lion much more than it does our domesticated cows, or other varieties of its own species. (Aiton.)

677. The diversity of qualities in the cow family is also very great. Our cows are so gregarious and inactive, that they scarcely know the road from their stall to their pasture; while those of the Hottentots are so tractable as to be intrusted with the charge of other animals, and keep them from trespassing on the fields of grain, or other forbidden ground. They also fight the heaviest of beasts, and gore heifers and oxen with their horns. Our dairy cows are so t e e l e and inactive, that they are hurt by travelling twice a day, even slowly, one mile from the byre to their pasture; while those of Tartary are used as riding animals, and in drawing carriages. Those of Hindostan draw the coaches, and maintain their rates with horses at the full trot; and the Hottentots teach their cows to hunt down elk antelopes. Cows of a small, neglected breed can with difficulty be removed from one enclosure or one hill to another; while those on whom due attention has been bestowed are docile, and submit to perform all sorts of labour. Some cows will yield upwards of twenty Scots pints of milk per day, while others will not give so much in ten, perhaps not in twenty days. These are not so many different species of animals, but all of them one and the same species, all capable of generating with each other a perfect offspring. All these varieties have been formed from the parent stock, partly by the diversity of soil and climate, or other accidental or adventitious circumstances; and partly of late by human skill and industry. (Dairy Husbandry.)

678. The varieties of the cultivated ox are the European, Indian, Zebu, Surat, Abyssinian, Madagascar, Tinian, and African. From the European variety have been formed the different breeds cultivated in this country; and the most celebrated of these breeds are generally distinguished by the length or flexure of their horns; by the absence of horns; by the districts where they are supposed to have originated, or in which they abound, or exist in the greatest purity; or by the name of the breeder.

679. The long-horned or Lancashire breed of cattle (Fig. 854.) is distinguished from others by the length of their horns, the thickness and firm texture of their hides, the length and closeness of their hair, the large size of their hoofs, and their coarse, leathery, thick necks; they are likewise deeper in their fore quarters, and lighter in their hind quarters, than most other breeds; narrower in their shape, less in point of weight than the short horns, though better weighers in proportion to their size, and though they give considerably less milk, it is said to abound more cream in proportion to its quantity. They are more varied in their colour than any of the other breeds; but, whatever the colour be, they have in general a white streak along their back, which the breeders term finched, and mostly a white spot on the inside of the hough. (Culley, p. 53.) In this vulgar name this race is not without the sim.

pular efforts that have been made towards its improvement, remains with little alteration, for, except in Leicestershire, none of the subvarieties (which differ a little in almost every one of those counties where the long horns prevail) have undergone any radical change or any obvious improvement. The improved breed of Leicestershire (Fig. 853.) is said to have been formed by W. Elster, of Cauley, near Coventry, in Warwickshire, by means of six cows brought from the banks of the Trent, about the beginning of the present century, which were crossed with bulls from Westmorland and Lancashire. Bakewell, of Dishley, in Leicestershire, afterwards got the head as a breeder, by selecting from the Cauley stock; and the stocks of several other eminent breeders have been traced to the same source. (Marshall's Midland Counties, vol. i. p. 318.)

680. The short-horned, sometimes called the Dutch breed (Fig. 566.), is known by a variety of names, taken from the districts where they form the principal stock, or where some of the breeders reside. As the Tees, or the head of the vale of York, is at present in the highest estimation, and is alleged to be the true Yorkshire short-horned breed, bulls and cows from this stock, purchased at most extraordinary prices, are spread over all the north of England, and the border counties of Scotland. The bone, head, and neck of these cattle are fine; the hide is very thin; the colour is dark brown; the loin broad; the carcase throughout large and well fashioned; and the flesh and fatting quality equal, or perhaps superior, to those of any other large breed. The short horns give a greater quantity of milk than any other cattle; a cow usually yielding twenty or thirty quarts of milk per day, making three firkins of butter during the grass season: their colours are much varied, but they are generally red and white mixed, or what the breeders call flecked. The heaviest and largest oxen of the short-horned breed, when properly fed, virtual the East India ships, as they produce the thickest beef, which,
by retaining its juices, is the best adapted for such long voyages. Our royal navy should also be victualled from these; but, from the jobs made by contractors, and the impure cattle often fed with beef of an inferior quality; however, the coal ships from Newcastle, Shields, Sunderland, &c., are wholly supplied with the beef of these valuable animals. These oxen commonly weigh from 60 to 140 stone (14 pigs to the stone), and they have several times been fed to 120, 130, and some particular ones to upwards of 150 stone, the fore-quarters only. (Culley, p. 48.)

6781. In comparing the breeds of long and short horned cattle, Culley observes that the long-horns excel in the thickness and firm texture of the hide, in the length and closeness of the hair, in their beef being finer-grained, and more mixed and marked; but they are inferior to the short-horns, in which the excellence of portion to their size, and in giving richer milk; but they are inferior to the short-horns, in giving a less quantity of milk, in weighing less upon the whole, in affording less tallow when killed, in being generally slower feeders, and in being coarser made and more leathery or tough in their flesh. In a few words, says he, the long-horns excel in the fine hide, hair, and quality of the beef; the short-horns in the quantity of beef, tallow, and milk. Each breed has long had, and probably may have, its particular advocates; but if he may hazard a conjecture, it is not probable that both kinds may have their particular advantages in different situations. Why not the thick firm hide, and the coarser set hair, of the long-horned, and the protection and security against those impetuous winds and heavy rains to which the west coast of this island is so subject; while the more regular seasons and mild climate upon the east coast are more suited to the constitutions of the short-horns? (p. 51.)

6782. The middle-horned breeds comprehend, in like manner, several local varieties, of which the most noted are the Devon, the Sussex, and the Herefords; the last two, according to Culley, being varieties of the first, though of a greater size, the Herefords being the largest. These cattle are the most esteemed of all our breeds for the draught, on account of their activity and hardihood; they do not milk so well as the short-horns, but are not deficient in the valuable property of feeding at an early age, when not employed in labour.

6783. The Devonshire cattle (fig. 857.) are of a rich red colour. If any white spots they reckon the breed impure, particularly if those spots run one into another, with a light dun ring round the eye, and the muzzle of the same colour; fine in the bone, clean in the neck, horns of a medium length, thick up to the middle, and fine in the knobs, in the hips, a tolerable barrel, but rather flat on the sides, tall and set, and on very high; they are thin-skinned, and silky in hand; feed at an early age, or arrive at maturity sooner than most other breeds. (Culley, p. 51.) Another author observes, that they are a model for all persons who breed oxen for the sword. (Parkinson on Liv. Stock, vol. i. p. 112.)

6784. Lawrence says that the race of red cattle of North Devon and Somerset is doubtless one of our original breeds, and one of those which have preserved most of their primitive form: this form for labour is best proved by the fact, that the fashionable substitution of horses has made no progress in the district of these cattle, by their high repute as feeders, and for the superior excellence of their beef, which has been acknowledged for ages. They are, he says, the speediest working oxen in England, and will trot well in harness; in point of strength, they stand in the fourth or fifth class. They have a greater resemblance to deer than any other breed of cattle. They are rather wide than middle-horned, as they are sometimes called; some, however, have regular middle-horns, that is, neither short nor long, turned upward and backward at the points. As milkers, they are so far inferior to both the long and short horns, both in quantity and quality of milk, that they are certainly no objects for the regular dairy, however pleasing and convenient they may be in the private family way.

6785. The Sussex and Herefordshire cattle (fig. 858.) are of a deep red colour, with fine hair and very thin hides; neck and head clean, the face usually white; horns neither long nor short, rather turning up at the points; in general, though they are well made in the hind quarters, wide across the hips, rump, and sirkon, but narrow in the chine; tolerably straight along the back, ribs too flat, thin in the thigh, and bone not large. An ox, six years old, will weigh, when fat, from 60 to 140 stone, the fore-quarters generally the heaviest; the oxen formerly worked from three to six years old, sometimes till seven, when they are turned off for feeding. The Hereford cattle are next in size to the Yorkshire short-horns; both this and the Gloucester variety are highly eligible as dairy stock, and the females of the Herefords have been found to fatten better at three years old than any other breed except the spayed heifers of Norfolk.

6786. The polled or hornless breeds. The most numerous and esteemed variety is the Galloway breed (fig. 859.) which is peculiar to the province of south-west of Scotland, where they most abound. The true Galloway bullock "is straight and broad on the back, and nearly level from the head to the rump, broad at the loins, not, however, with hooked bones, or projecting knobs, so that when viewed from above, the whole body appears beautifully rounded; he is long in the quarters, but not broad, he is deep in the chest, short in the leg, and moderately fine in the bone, clean in the chop and in the neck; his head is of a moderate size, with large rough ears, and full but not prominent eyes, or heavy eyebrows, a calm though determined look, his well proportioned form is clothed with a loose and mel- low skin, adorned with long soft glossy hair." (Galloway Report, p. 259.) The dark brimplied, and, though they are occasionally found of every colour, the dark colours are uniformly preferred, from a belief that they are connected with superior hardihood of constitution. The Galloways are not so large as the other breeds from the size of the head, but as much less than the long-horns, as the long-horns are less than the short-horns. On the best farms,
under similar soil, climate, and relative circumstances; but also in feeding, for the shambles. They are, in fact, breeders that have received, careful feeding, careful feeding, and treatment, been improved and brought to a state of perfection, which fits them, above all others yet known, to answer almost in every diversity of situation, where grain and grasses can be raised to feed them, for the purposes of the dairy, or for fattening them for beef. (Aiton.)

6790. The origin of the Ayrshire breed of cattle is to be found in the indigenous cattle of the county of Ayr, "improved in their size, shapes, and qualities, chiefly by judicious selection, cross-coupling, feeding, and treatment, for a long series of time, and with much judgment and attention, by the industrious inhabitants of the county, and principally by those of the district of Cunningham." (Aiton.) The whole dairy breed in the county of Ayr is of mixed white and brown colours.

6793. The form of the Cunningham Ayrshire cow, according to Robertson, is "very elegant, but must be seen to be well understood. So far as it may be explained in words, it is as follows: — The neck is small, the head little, the muzzle taper, the horns short, curved, and bending upwards. The ears are long and drooping, the countenance mild, and the ears straight along the back from shoulder to tail; the limbs slender; the udder shaped like a well turned punch-bowl, and the paps widely set. The head, the neck, and the udder are the chief distinguishing parts. The fleece is generally brown, of many hues, from dark to fawn, intermixed with more or less white. Some have a dark ground, without any change in character; but almost none are of one colour only. In a white herd of forty or fifty, there will not two of them be alike in colour, in this respect exhibiting a diversity not unlike to a bed of tulips, and of as many different shades and tints. The udder is a flagrant variety of beauty. The udder is generally good tempered, and, like the cows, are also mild in the countenance. The usual produce of butter from these cows is ascertain to be about half their own weight (meaning the four quarters) in a year; but this requires that the pasturage be good, and the cow otherwise well kept the whole season over. The produce of such a cow as will keep well sends 225 to 240 pounds of butter, at the moderate price of 7s. 6d. per quarter, to keep that quality of cheese. The medium produce in butter from Ayrshire milk is from five imperial quarts. (Rural Recollections, p. 550.)

6794. The qualities of an Ayrshire dairy cow are of great importance. Tameness and docility of temper, and of milk, are the two most important qualities. One that is quick and contented at ease, does not break over fences, or hurt herself and other cattle, will always yield more milk, and is easier to manage, than those that are of a turbulent disposition. To render them docile, they ought to be gently treated; frequently handled when young, and never struck or frightened. Some degree of hardness, a sound conformation, and a good disposition, are qualities to be wished for in a dairy cow, and what those of Ayrshire generally possess. The most valuable quality which a dairy cow can possess is that she yields much milk. A cow in Ayrshire that does not milk well will soon come to the end of her time; if a cow has never seen cows, and is here that, under the same mode of feeding and treatment, will yield so much milk as the dairy breed of that district. Ten Scotch pints per day is no way uncommon. Several cows yield, for some time, twelve pints, and some thirteen or fourteen pints per day. Another quality of the
dairy breed of Ayrshire is, that, after they have yielded very large quantities of milk for several years, they are as valuable for beef as the Galloway cow, or, Scotland. Their cows are of large size, and fatten as well, and their beef is not inferior to that of any other breed of cattle known in Britain." (*Aiton."

679. The cattle of the Highland of Scotland are divided into a number of local varieties, some of which differ materially from others, probably owing to a difference in the climate and the quality of the pasture, rather than to their being sprung from races originally different. A great improvement has been made in the selection or by crossing with other breeds. It is only of late that much attention has been paid to their improvement, in any part of this extensive country; and in the northern and central Highlands the cattle are yet, for the most part, in rude a state, and unhappily many of them are but little improved. The numbers of these cattle have, however, increased of late years in some places very considerably. In the north, the Highland cattle are intermixed with various local breeds, of which they have probably the basis. There are more or less marked distinctions among the cattle of the different Highland counties; and, in common language, we speak of the Inverness-shire, the Banffshire, A.?., and the like. It is not so in some separate breeds; in others, they have three or more general varieties, now clearly distinguishable by their form, size, and general properties.

679. The most valuable of these are the cattle of the Western Highlands and Isles, commonly called the Fifeshire cattle (fig. 861.), or the English race of Skye, one of the islands attached to the county of Argyle. The cattle of the Hebrides are called *kyloes*, a name which is often applied in the south to all the varieties of the Highland cattle, not as a late writer (*Dickson's Practical Agriculture*, vol. ii. p. 1134.) has imagined, from the district in Ayrshire called Kyle, where very few of them are kept, but from their crossing, in their progress to the south, the *kyloes* or ferries in the mainland and Western islands, where these cattle are found in the greatest perfection. (*General Report of Scotland*, vol. iii. p. 265.)

679. The cattle of Orkney and Zetland are of a most diminutive size; an ox weighing about sixty pounds a quarter, and a female of fifty pounds. They are of all colours, and their shapes are generally bad: yet they give a quantity of excellent milk; fatten rapidly when put on good pastures; and, in their own district, are considered strong, hardy, and excellent workers, when well trained to the yoke, and so plentifully fed as to supply the necessary amount of milk to the farms. The hardy cattle of the Scilly Isles, of which there are some at St. Mary's, and which are considered a much more valuable breed, are of a lighter and more spirited character, and would be more highly esteemed if they could be protected from those which, by long-inbreeding, have become extremely abraded. The cattle of the southern Hebrides, of Barra, isles, are not of the same good feed; but the cattle of the Scilly Isles and of the Kerrera are considered very good, and are much esteemed where they are kept for the sake of their milk, which is very rich, though small in quantity. This race is considered, by very competent judges, as too delicate and tender to be propagated to any extent in Britain, at least in its northern parts. Their colour is light red, with white hide, with long hairs, and very thin in faces; they have short crumpled horns, of small size, and very ill-shaped; yet they are fine-boned in

680. Of the Welsh cattle (fig. 862) "there seem to be two distinct kinds. The large sort are of a brown colour, with some white on the rump and shoulders, denoting a cross from the long-horns, though not as much in the shape of horns, and not the least resembling them. They are long in the legs, stand high according to their weight, are thin in the thigh, and rather narrow in the chest; their horns are very long, turned upwards; they are light in flesh, and next to the Devons, well formed for the yoke; have very good hoofs, and walk light and nimble. The other sort are much larger, with a darker colour black, with very little white; of a good useful form, short in the leg, with round deep bodies; the hide is raised of a yellowish short hair, with a good look, and a good eye; and the bones, though not very small, are neither large nor clumsy; and the cows are considered good milkers." (*Parkinson on Live Stock*, vol. i. p. 135.)

681. The cattle of the Western Highlands and Isles are divided into several varieties: the Ayrshire and the Banffshire breeds, for instance, have very little resemblance in their appearance. The former are of a dark brown, with a dun or greyish body, and a very light head, with long shaggy hair, and short hair on the sides; the latter are of a light brown, with a much lighter head, and much finer hair. The Ayrshire cattle are considered the most valuable of the Western Highland breeds, and are much esteemed for their milk, which is very rich, though small in quantity. They are also much valued for their meat, which is very tender, and very much esteemed for their breed, and are considered very valuable for the sake of their milk, which is very rich, though small in quantity. This race is considered, by very competent judges, as too delicate and tender to be propagated to any extent in Britain, at least in its northern parts. Their colour is light red, with white hide, with long hairs, and very thin in faces; they have short crumpled horns, of small size, and very ill-shaped; yet they are fine-boned in
general; and their beef, though high-coloured, is very well flavoured. I have seen, says Culley, some very useful cattle bred and horned cross between an Alderney cow and a short-horned bull.

6803. The Irish cattle, Culley thinks, are a mixed breed between the long-horns and the Welsh or Scotch, but more inclined to the long-horns, though of less weight than those in England.

6804. The last variety of cattle we shall mention is one entirely of luxury, it is the wild breed (fig. 863) which is found only in the parks of a few great proprietors, who preserve the animals as curious and ornamental, or for the sake of their high-flavoured beef. These kept at Chillingham Castle, in Northumberland, a seat belonging to the Earl of Tankerville, have been very accurately described in the Northumberland Report, and in Culley's book on live stock, so often quoted. Their colour is invariably of a cream-white; muzzle black; the whole of the inside of the ear, and about one third of the outside, from the tips downward, red; horns white, with black tips, very fine, and bent upwards; some of the bulls have a thin upright mane, about an inch and a half or two inches long. The weight of the oxen is from thirty-five to forty-five stone, and the cows from twenty-five to thirty-five stone the four quarters (fourteen pounds to the stone). The beef is finely marbled, and of excellent flavour. From the nature of their pasture, and the frequent agitation they are put into by the curiosity of strangers, it is scarcely to be expected that they should get very fat; yet the six years old oxen are generally very good beef, from which it may be fairly supposed that, in proper situations, they would feed well.

6805. The habits of these animals are entirely rude; at the first appearance of any person they set off in full gallop, and at the distance of about two hundred yards, make a wheel round and come boldly up again, tossing their heads in a menacing manner; on a sudden they make a full stop, at the distance of forty or fifty yards, looking wildly at the object of their surprise, but, upon the least motion being made, they all again turn round, and fly off with equal speed, but not to the same distance, forming a shorter circle, and again returning with a bolder and more threatening aspect than before; they approach nearer, probably within thirty yards, when they again make another stand, and again fly off; this they do several times, shortening their distance, and advancing nearer and nearer till they come within such a short distance, but at such a make it prudent to leave them, not choosing to provoke them farther.

6806. When the cows calve, they hide their calves for a week or ten days in some sequestered situation, and go and suckle them two or three times a day. If any person comes near them, the calves clap their heads close to the ground, and lie like hares in form, to hide themselves. This is a proof of their native wildness, and is corroborated by the following circumstance that happened to the writer of this narrative (Bailey of Chillingham) who found a hidden calf, twodays old, very lean and very weak: On straining its head it got up, pawed two or three times like an old bull, bellowed very loud, stopped back a few steps, and bolted at his legs with all its force; it then began to paw again, bellowed, stepped back, and bolted as before; but knowing its intention, and stepping aside, it misjudged him, fell, and was so very weak that it could not rise, though it made several efforts; but it had done enough: the whole herd were alarmed, and, coming to its rescue, obliged him to retire; for the dams will allow no person to touch their calves without attacking him with impetuous ferocity.

6807. When a calf is to be castrated, the park-keeper marks the place where it is hid, and when the herd are at a distance, takes an assistant with him on horseback; they tie a handkerchief round the calf's mouth to prevent its bellowing, and then perform the operation in the usual way, with as much expedition as possible. When any one happens to be wounded, or is grown weak and feeble through age or sickness, the rest of the herd set upon it and gore it to death. (Culley, p. 73.)

6808. The mode of killing them was, perhaps, the only remains of the grandeur of ancient hunting. On notice being given that a wild bull would be killed on a certain day, the inhabitants of the neighbourhood came armed with guns, &c. sometimes to the amount of a hundred horse, and four or five hundred foot, who stood upon walls or went into trees, while the horsemen rode off from the bull from the rest of the herd, until he stood at bay, when a marksman dismounted and shot. At some of these huntsings, twenty or thirty shots have been fired before he was subdued. On such occasions, the bleeding virtuoue grew desperately furious from the smarting of his wounds, and the shouts of savage joy that were echoing from every side; but, from the number of accidents that happened, this dangerous mode has been little practised of late years, the park-keeper alone generally shooting them with a rifle gun at one shot.

SUBSECT. 2. Criteria of Cattle for various objects and purposes.

*6809. The criteria of a well-made bull, to whatever breed he may belong, are, according to Culley, as follows:—The head should be rather long, and the muzzle fine; his eyes lively and prominent, his ears long and thin, his horns wide, his neck rising with a gentle curve from the shoulders, and his neck as high and full as possible, and his shoulders moderately broad at the top, joining full to his chine or crops and chest backwards, and to the neck vein forwards; his bosom open, breast broad, and projecting well before his legs; his arms or fore-thighs muscular, and tapering to his knee; his legs straight, clean, and very fine-boned; his chine and chest so full as to leave no hollows behind the shoulders; the plates strong, to keep his belly from sinking below the level of his breast; his back or loin broad, straight, and flat; his ribs rising one above another in such a manner that the last rib shall be rather the highest, leaving only a
small space to the hips or hooks, the whole forming a round or barrel-like carcass; his hips should be wide placed, round, or globular, and a little higher than the back; the quarters from the hip to the rump long, and instead of being sunk or recommended from the hips backward, and the tubs or part-bones not in the least protruberant; rump close to the tail, the tail broad, well haired, and set on so high as to be in the same horizontal line with his back. Bulls should be constantly well fed, and kept in proper enclosures, never being subjected to arise before they are three years old; but they are never at any time perfect a growth. It is observed by Law, that the above description delineates that barrel-shape which Bakewell supposed most advantageous for all kinds of animals intended to be fed for slaughter, or even used for labour.

681. The excellence of excellence of excellence in cattle to give experience by John Wilkinson of Linton, near Nottingham, an eminent breeder. (Remarks on Cattle, &c. 1828) "The head ought to be rather long, and muzzle fine; the countenance calm and placid, which indicates a disposition to get fat; the horns fine; the neck light, particularly where it joins the head; the breast wide and projecting well before the legs; the shoulders moderately broad at the top, and the joints well in, and when the animal is in good condition, the chine so full as to leave no hollow behind it; the fore flank well filled up, and the girth behind the shoulders deep; the back straight, wide, and flat; the ribs broad, and the space between them and the hips small; the flanks full and heavy; the loins broad, and not sinking low in the middle, but so formed that a cross section of it would resemble an oval, whose two ends are of the same width, and whose form approaches to that of a circle, or of an ellipse whose eccentricity is not great (the whole ellipse in the case of calves) for young bullocks; the ribs being so formed as some would term barrel-shaped, more than round, but so not giving the appearance of a boat; the tail point and rump points fat, and coming well up to the tail; the twist wide, and the scame in the middle of it so well proportioned to the whole body that the animal appears a perfect whole of the largest part of the thighs; the tail broad and fat towards the top, but the lower part thin; the legs straight, clean, and fine-boned; and when the animal is in high condition, the skin of a rich and silty appearance. The head should be the most material point for the formation of true cattle; and when there are others of a part, which will readily be suggested by attention and experience."

681. The criteria of an ox well adapted to labour differ from the above only in requiring long and strong legs, and broad hardy feet and hooves.

She's long in her face, she's fine in her horn, she'll quickly get fat, without cake or corn, she's clear in her jaws, and full in her chin, she's heavy in flank, and wide in her loin.

She's broad in her ribs, and long in her rump, A straight and flat back, with never a hump; She's wide in her hips, and calm in her eyes, She's fine in her shoulders, and thin in her thighs.

She's light in her neck, and small in her tail, She's wide in her breast, and good at the heel, She's fine in her bone, and silty of skin, She's a grazer's without, and a butcher's within.

681. Culley's marks of a good cow are these:—Wide horns, a thin head and neck, dwelap large, full breast, broad back, large deep belly; the udder capacious, but not too fleshy; the milk veins prominent, and the bag tending far behind; teats long and large, buttocks broad and fleshy, tail long and pliable, legs proportionable to the size of the animal, and the joints properly set in. To these outward marks may be added a gentle disposition, a temper free from any vicious tricks, and perfectly manageable on every occasion. On the other hand, a cow with a thick head and a short neck, prominent back-bone, slender chest, belly tucked up, small udder or small teats, and short, flat, or dry horns, will not answer for the purposes of either the dairy-man, the suckler, or the grazer. The most valuable cows are those which are bred in Yorkshire, Staffordshire, and upon the strong lands in other part of England, and in Arrhulence in Scotland.

681. The criteria of excellence in cattle, as derived from colour, are of no importance; and all that can be said is, that white and red cattle are less hairy than the black-haired.

681. The criteria of age in cattle are derived from the teeth and horns. At the end of about two years they shed their first four teeth, which are replaced by others, but not so white; and before five years all the incisive teeth are renewed. These teeth are at first equal, long, and pretty white; but, as the animals advance in years, they wear down, become unequal, and grow black. These animals, according to some, likewise shed their horns at the end of three years; and they are replaced by other horns, which, like the second teeth, continue; this, however, is totally or partially denied by practical men, and their statement of it as a fact without qualification has been objected to in the "American Farmer." The manner of the growth of these horns is not uniform, nor the shooting of them equal. First, that year, that is, the fourth year of the animal's age, two small-pointed horns make their appearance, neatly formed, smooth, and towards the head terminated by a kind of button. The following year this button moves from the head, being impelled by a horny cylinder, which, lengthening in the same manner, is also terminated by an animal button and so on; for the horns continue growing as long as the animal lives. These buttons become longer, and are called horns or ears, and are, in fact, a peculiarly distinguished in the horn, and by which the age of the creature may be easily known; counting three years for the point of the horn, and one for each of the joints or rams. The cow continues useful for more than twenty years, but the bull very nearly effects as much service. As an old animal, both are common with dealers to adjust these horns, by shaving the horns, in order to conceal the age of the beast.

681. The objects applied to different ages are as follows:—A young castrated male, after the first year, is called a stick; when a year older, is called a stigkeit, or, slot, or stecker, and at five years, old, an ox. A female, after the first year, is called a heifer, or quiet; when about to bring a calf, she is called a young. A castrated female is called a spayed heifer. Certain of the Welsh and Scots cattle, of rather a coarse and sturdy kind, are denominated ronts. Bullock is the general term for any full-grown male cattle, fat or lean.

681. The natural duration of life of cattle, with the bolt and bull, and bull and cow, is about fifteen years, to nearly the end of which the latter is useful with her milk, but the former generally loses his vigour, consequently his use, many years sooner.

SUBJECT 5. Breeding of Horned Cattle

681. The objects to be kept in view in breeding cattle are, forms well adapted for fattening, for producing milk, or for labour. These three objects have each of them engaged the attention of British agriculturists; but experience has not hitherto justified the expectation that has been entertained of combining all these desirable properties, in an eminent degree, in the same race. That form which indicates the property of yielding the most milk, differs materially from that which we know from experience to be combined with early maturity and the most valuable carcass; and the breeds which are understood to give the greatest
weight of meat for the food they consume, and to contain the least proportion of offal, are those which possess, in the highest degree, the strength and activity required in the beasts of labour.

681. A disposition to fatten, and a tendency to yield a large quantity of milk, cannot be united. The form of the body at maturitv for the dairy is very different from that of the other; in place of being flat in the sides, and big in the belly, as all great milkers are, it is high-sided and belted; in a word, the body of the animal well adapted to fatten is barrel-formed, while that of the milker is widest downwards. It is impossible, therefore, that the possession of two breeds of cattle, so opposite in form and general appearance, can ever be united in the same animal.

682. The long and short horned breeds have hitherto been in possession of the best part of the island; but various others, as the Ayrshire, the Teviot, and the Northumberland, are now as general as they were at first; and, so to speak, might be divided into cattle, and kind of cattle, as they are the true quick-feeders, and being kindly-fed, or excellent eating beef, have established their character in the market in the island. The Scotch or kyloes are better adapted to cold, exposed, healthy ground, where the short breed we have spoken of is not adapted to particular situations; on which ground, breeders of cattle should endeavour to find out what breed is the most profitable and best suited to their situations, and to improve that breed to the utmost, rather than to be forced to choose between two or more distant qualities, the best adapted to particular situations; for we generally find the produce inheriting the coarseness of both breeds, and rarely attain the good properties which the pure distinct breeds individually possess. In order to have good cattle of any breed, particular regard must be paid in selecting those that are the most complete and perfect in their form, shape, and other qualities, and to breed from them.

683. An extraordinary degree of attention has been paid to the breeding of cattle in England since the time of Bakewell, and some illustrious names might be mentioned in addition to those of professional farmers. Pedigrees of the best cattle have been preserved with no less care, in several places, than those of race horses; and, in the selection of breeders, the properties of the family from which they have descended are matters of scarcely less importance than the form of the young animals themselves. The extraordinary prices paid for the best-bred bulls and cows show that this attention has not been without its reward.

684. The best bulls are either let out for the season, or cows are brought to them at a certain rate per head. The practice of letting bulls is said to have originated with Bakewell (Marshall's Midlothian, vol. i. p. 125; vol. ii. p. 86); and five guineas per cow were about that time commonly paid to him and other eminent breeders.

685. The age at which bulls should begin to be employed, and the number of seasons they should be allowed to do so, as well as the age at which the females should begin to breed, are points regarding which practice is by no means uniform. In the midland counties, the bulls are pretty commonly allowed to leap while�ears; and if good stock-getters are kept on as long as they will do business, the best bulls are employed only for three or four seasons, and are emplaced in other places, as breeders of the first time at two years old. The females, in many instances, bring their first calf at the age of two years, but more commonly perhaps, not till they are a year older; and in some of the Highland districts, where, owing to a want of proper nourishment in their infancy, they are later in coming to their full growth, the females do not often become mothers till they are about four years old.

686. The period of gestation with cows has been found, upon an average of a great number of experiments, to be about forty weeks. M. Tessier communicated to the National Institute of France the following statements on this subject: 11 calves were brought from the 24th to the 29th day; 5 on the 27th; 5 on the 28th; 6 on from the 28th to the 30th; 20 on the 30th; and 5 on the 30th. Cows seldom bring more than one calf at a time. When they produce twins, one of them a male and the other a female, the latter, which is commonly called the bull calf, is reared at the expense of the bull. In a few cases, twins are reared, and have been well authenticated instances to the contrary. (Farmer's Magazine, vol. vii. p. 622; and vol. viii. p. 466.)

687. The most desirable period for parturition to the bull is midsummer, in order that they may be dropped in spring, and have the whole of the grass season before them. Where no regular system is followed, and cows are sent to the bull merely because they are in heat, calves will be dropped at all seasons; but, except in those districts where the fattling of calves is an object of importance, spring is probably the most advantageous time; as the calves, having all the grass season before them, become sufficiently strong for enduring the change to a less agreeable food in the ensuing winter. A calf newly weaned seldom thrives well during that period, unless it is pampered with better food than usually falls to the share of young animals. By midsummer the cows are ready to the bull than at any other season, and the calves are in proper condition. Some of them have gone till after May before they calve, the calf will be too weak in the winter following; and the dam will be not so ready to take the bull again, but will often grow barren.

688. It is not always the best milch cow that has the best calf, even though the external circumstances should be similar; and vice versa, a sorry cow may have a good calf. These remarks apply to this breed as well as to others. The immediate progeny of a good milker may be a magnificent milch cow; but in the second remove, the good milking quality of the grandam returns. This has often been observed, and without any of the causes being imputable to the size. (Roberto, p. 57.)

SUBSECTION 4. Rearing of Horned Cattle.

689. The mode of rearing calves is various. There can be little doubt but that the best and most natural mode is that of allowing them to suck their dams, at least for some length of time after they are brought forth.

690. In Yorkshire, and most parts of Scotland, the usual method is to give them milk to drink, there being few instances where they are allowed to suck. For the first two or three weeks, they are fed with milk, if not twice a day, at least three times a day. In half the milk is withdrawn, and skim-milk substituted in its stead; and at the end of that period, the new milk is wholly withdrawn; they are then fed on skim-milk alone, or sometimes mixed with water, till they are able to support themselves by eating grass, or other food that grows in the lawn.

691. In Cheshire, the practice is to allow the calves to suck for the first three weeks. They are then fed on warm new milk, or scalded whey and buttermilk mixed; with the green whey water is frequently mixed, and either oatmeal or wheat and bean flour added. A quart of oatmeal or flour is given to a calf; and a quart of skimmed milk to a bull calf. Oatmeal and barley meal, with an addition of skimmed milk, are also used for the same purpose. One of these prepared kinds of food is given, night and morning, for a few weeks after the calves are put on that diet, but afterwards only once a day till they are three months old or more.

692. In Gloucestershire the calves are not allowed to suck above two or three days; they are then fed on skim-milk, which is previously heated over the fire. When they arrive at such an age as to be able to eat a little, they are allowed split beans, or oats and cut hay, and when the calves are well grown, are put on grain. At the end of three or four, and give them a liberal allowance of skim-milk for six or eight weeks longer.

693. In Middlesex it is usual, in rearing calves, to give them a pailful, containing about a gallon, of milk warm from the cow, morning and evening, for eight or ten weeks; or, which is certainly the most
agreed to nature, and therefore to be preferred to any other that can be adopted, to allow the calf to suck its dam, as it is sometimes done in the county of Sussex, and generally in Wigtownshire.

653. According to Marshal, the best method is this:—The calves suck a week or a fortnight, according to their strength (a good rule); new milk in the pail, a few meals; next, new milk and skim milk mixed, a far less quantity than with water, then, water, and, if the calf is well, or porridge or meal with water, or occasional times oil-cake, until cheese-making commences; after which, whey, porridge, or sweet whey, in the field, being careful to house them in the night, until warm weather befall; (Moundl Countles, vol. i. p. 186.) without water, however, feeding is not done, or, at least, it is a great deal to rearing calves, it is to be a preferable plan to begin at once to teach them to drink from a pail. The calf that is fed from the teat must depend upon the milk of its dam, however scanty or irregular it may be; whereas, when taken to a pail, much more regular, and the quantity can be regulated by the hand, may be resorted to, by which a great part of the milk is saved for other purposes, or a greater number of calves reared upon the same quantity. (General Report of Scotland, vol. iii. p. 51.) Yet it would seem to be a good practice to allow calves to suck for a few days at first, if there were no inconvenience to be apprehended from the severity of the weather, and their dams, from two to four weeks old, a greater proportion of milk is used in different places, of which luseeed-oil cake, meal, and turnips, are the most common.

683. Where calves are reared with skim milk, it should be boiled, and suffered to stand until it cools to the temperature of that first given by the cow, or a trilling degree more warm, and in that state it should be given to the calf. Milk is frequently given to calves warm only; but that method will not succeed so well boiling it. If the milk be given over cold, it will cause the calf to snot or purge. When this is the case, put two or three spoonfuls of rennet in the milk, and it will soon stop the boseness. If, on the contrary, the calf is bound, bacon broth is a very good and safe thing to put into the milk. One gallon of milk per day will keep a calf well at first. The usual allowance is about double after the first eight or ten days, and this is increased with the age of the animal. After it is thirteen weeks old, it may do very well upon grass or other food, without any milk at all. A calf may then be supported without milk, by giving it a teat, or a bit of hay about the wheat-braun, once or twice a day, with a common measure of water as soon as the calf is capable of eating them. The bran and oats should be given about mid-day, the milk in portions, at eight o'clock in the morning, and four in the afternoon. But whatever hours are chosen, it is best to start for feeding the calf, it is best to feed the calf with a teat late in the evening, or more consequence than many people think. If the calf go but an hour or two beyond his usual time of feeding, he will find himself uneasy, and pine for food. It is always to be understood, that calves reared in this manner are to be enticed to eat hay as early as possible; and the best way of doing this is to give them hay that can be eaten at that time, and little but little hay, as soon as they can be eaten by them; and they are best cut small, and mixed with hay, oats, bran, and such articles. It may be observed, that it is not absolutely necessary to give milk to calves after they are one year old; but it is very good to wean them gently, two quarters of milk to a pint of water, for milk, to make a gruel, given together, will answer; and by diminishing the milk gradually, the calf will soon do without it. Hay tea will do, with the like addition of two quarters of milk; but it is not so nutritious as a fine proportion of milk and milk, to put such a proportion of this to a tus, then to pour on a sufficient quantity of boiling water, which will keep the vessel, and let it remain long enough to extract the virtues of the hay. When bacon or pork is boiled, it is a good way to preserve the liquor or broth, and mix it with milk for the calves.

663. Calf's milk may sometimes be reared on warmer; but, when reared in winter, they must be fed with hay; and clover hay is probably the best of any for this use. Calves may also be raised with porridge of different kinds, without any mixture of milk. It is sometimes a good and convenient plan, the author of the Farmer's Magazine says, to bring up Charollais calves with a pint of mares milk; or two quart of milk, and two quarts of milk to a pint of water, as soon as they can be eaten by them; and they are best cut small, and mixed with hay, oats, bran, and such articles. It may be observed, that it is not absolutely necessary to give milk to calves after they are one year old; but it is very good to wean them gently, two quarters of milk to a pint of water, for milk, to make a gruel, given together, will answer; and by diminishing the milk gradually, the calf will soon do without it. Hay tea will do, with the like addition of two quarters of milk; but it is not so nutritious as a fine proportion of milk and milk, to put such a proportion of this to a tus, then to pour on a sufficient quantity of boiling water, which will keep the vessel, and let it remain long enough to extract the virtues of the hay. When bacon or pork is boiled, it is a good way to preserve the liquor or broth, and mix it with milk for the calves.

657. When calves are dropped during the grass season, Donaldson observes, they should be put into some small, close of sweet rich pasture after they are eight or ten days old, not only for the sake of exercise, but also to avoid the atrophy of sweet rich pasture after they are eight or ten days old, not only for the sake of exercise, but also to avoid the atrophy of the body; after they are about two months old, they may be turned to the better pastures of the meadow, to be fattened for market. Calves should be fed, and a tolerable stock of milk, but can be fattened by any milk, as the first and thinnest of the milk is sufficiently rich. Old milk will, perhaps, scour a very young calf; but the effect will go off without any ill consequences. He observes, that the Duke of Northumberland's recommendation of skimmed milk, and to about one quart of milk, or better to stir it until it is well mixed; then to take one ounce of linseed-oil cake, finely pulverised, and with the hand let it fall gradually, in very small quantities, into the milk, stirring it in the mean time with a spoon or ladle, until it be thoroughly incorporated; then let the mixture be put into the other part of the milk, and the calf will be made to drink it as warm as near as it could be at the time, and that that state it is fit for use. The quantity of oil-cake powder may, from time to time, be increased as much as may require, and as the calf becomes inured to the flavour of it. Crook's method is to make a jelly of linseed, boiled six minutes in six pints of water, and mixed with a small quantity of the best hay tea. On this he rears many calves without milk; he thinks many calves are annually lost by artificial rearing, and more brought up with poor and weak constitutions.

658. When calves are dropped during the grass season, Donaldson observes, they should be put into some small, close of sweet rich pasture after they are eight or ten days old, not only for the sake of exercise, but also to avoid the atrophy of sweet rich pasture after they are eight or ten days old, not only for the sake of exercise, but also to avoid the atrophy of the body; after they are about two months old, they may be turned to the better pastures of the meadow, to be fattened for market. Calves should be fed, and a tolerable stock of milk, but can be fattened by any milk, as the first and thinnest of the milk is sufficiently rich. Old milk will, perhaps, scour a very young calf; but the effect will go off without any ill consequences. He observes, that the Duke of Northumberland's recommendation of skimmed milk, and to about one quart of milk, or better to stir it until it is well mixed; then to take one ounce of linseed-oil cake, finely pulverised, and with the hand let it fall gradually, in very small quantities, into the milk, stirring it in the mean time with a spoon or ladle, until it be thoroughly incorporated; then let the mixture be put into the other part of the milk, and the calf will be made to drink it as warm as near as it could be at the time, and that that state it is fit for use. The quantity of oil-cake powder may, from time to time, be increased as much as may require, and as the calf becomes inured to the flavour of it. Crook's method is to make a jelly of linseed, boiled six minutes in six pints of water, and mixed with a small quantity of the best hay tea. On this he rears many calves without milk; he thinks many calves are annually lost by artificial rearing, and more brought up with poor and weak constitutions.
to their pasture, milk-pottage should be carried to them at each of their feeding hours. For the first month or six weeks, the calves ought every night to be brought out of the meadow, and lodged in the pens; but after this time they may be left in the pasture as well in the night season as in the day; and at this time their food may be lowered by degrees, till it consists at length rather of milk and simple water only; for, when the calves are of the age of twelve or fourteen weeks, they will no longer require the aid of water, but will be able to satisfy their appetites with grass. Care, however, must be taken throughout the summer that they be frequently shifted from one pasture to another, in order that they may be kept up in good flesh, and for the sake of the country. At Michaelmas, they may be brought into the parlor, or secured in the dairy, and milked as they are to be taken into the yard; and if they were allowed the indulgence of a small close to themselves it would be still better.

6541. The treatment of young cattle, from the time they are separated from their dams or are able to subsist on the common food of the other stock, must entirely depend upon the circumstances of the farm on which they are reared. In summer, their pasture is often coarse, but abundant; and in winter all good breeders give them an allowance of succulent food along with their dry fodder. The first winter they have hay and straw, giving them two or three times as much straw as hay. In the second winter, they give them straw once a day, in an adjoining field, just sufficient to prevent the straw from binding them too much; the next winter tolerably good pasture; and the third winter as many turnips as they can eat, and are able to benefit from them, as stated in the following paragraph, p. 424.

6542. The method of managing young cattle during the first winter, is, according to Donaldson, pretty generally the same in every part of the island. They are generally housed; sometimes found up to the stall; but more frequently allowed to remain at freedom. The way of feeding them in England is chiefly by hay or hay and straw mixed, and sometimes with hay, but more frequently straw and turnips. They are mostly turned out on some of the inferior pastures on the farm in the following summer, and maintained the second winter on straw in the straw-yard, or in houses or sheds erected for the purpose. Some farmers in the more norther parts of the island turn them out at a distance from any market at which they can dispose of stall-fed beef, very frequently give a considerate part of their turnip-crop to their young cattle. This is, he thinks, an excellent practice; and one that ought to be followed, with the greatest advantage, both for the comfort of the young cattle, and for the improvement of the farm. The author of the Treatise on Husbandry observes, that as it is necessary that the calves should live always quiet, in order that they may indulge in sleep at those times when they are not employed in sucking, it seems proper that the cow-house should be situated in the most retired part of the yard, and that the pens should be kept as quiet as possible. But notwithstanding this caution, the calves should by no means be suffered to lie too hot in the summer time, which would be apt to produce a sickness amongst them. To admit, therefore, an occasional draught of fresh air, let a window be cut in each pen, with shutters adapted to the same, and let each pen be situated where the atmosphere is free from dust and filth. In the summer season, they should rarely, if ever, be closely shut; and when it is required, the stream of air may be increased by opening the cow-house door at the opposite end of the building. Each calf should have a collar round his neck, with which the attendant may direct him in his sucking, but should never be fastened up in the pen. It is expedient that the pens be kept constantly well littered with the cleanest straw, a proportion of which should be thrown in to every day; cleanliness being a most essential article in the fattening of every animal, and more necessary to any than to a calf, which, being in a small space, concentrates the ill effects of an over-laying on his accumulated dung, which of all animals is the most offensive and of a quality highly septic. As the calves are yeaned, they are to be taken into the pens, and suckled by their own dams, which at first will yield a far greater quantity of milk than is necessary for their offspring, so that another calf may be suckled thereon; or the cow may be milked, and the cream be reserved for butter, or applied to any other use that the owner may think proper. As the calf increases in size, it will require a larger quantity of milk; but whilst calves are young, one good cow will yield a noble supply for two; and when the whole produce is demanded for one calf, which is the case in a further stage of growth, and these two cows will abundantly supply the three calves with milk till the oldest is fit for the butcher; after which, if necessary, a fresh suckler may be brought in, and the business be carried on progressively by keeping the house constantly supplied with calves, so that the whole milk may be sucked, as the dairy and the fattening of calves by sucking cannot be conveniently united.

6543. The most advantageous stock for sucking calves for the butcher is that sort of cow which gives the greatest quantity of milk, richness of quality being not so great an object, or so well adapted to the desired purpose. The Holderness cows are to be preferred in this view; not, however, to suckle calves of the same breed. The young cattle surpass all others as sucking, for richness of proof, or beauty of the veal; they are not, however, to be procured but in or near their own country.

6544. The method most commonly employed in fattening calves, is, to allow them to suck; as by this method the object is probably not only sooner, but more effectually attained than by any other means. The period which is necessary for fattening calves in this way must be different, according to circumstances, but it is generally from seven to nine weeks; however, when the fattening can be considered in any degree as a matter of necessity, an additional period of the same time is allowed. These are another method, which is, to give them the milk to drink; and when that is done, it is given them morning and evening warm from the cow, and the quantity increased according to their age and strength. In whatever way they may be managed, the cow-house, and well-lit shed, in the author of the Treatise on Husbandry observes, that as it is necessary that the calves should lie always quiet, in order that they may indulge in sleep at those times when they are not employed in sucking, it seems proper that the cow-house should be situated in the most retired part of the yard, and that the pens should be kept as quiet as possible. But notwithstanding this caution, the calves should by no means be suffered to lie too hot in the summer time, which would be apt to produce a sickness amongst them. To admit, therefore, an occasional draught of fresh air, let a window be cut in each pen, with shutters adapted to the same, and let each pen be situated where the atmosphere is free from dust and filth. In the summer season, they should rarely, if ever, be closely shut; and when it is required, the stream of air may be increased by opening the cow-house door at the opposite end of the building. Each calf should have a collar round his neck, with which the attendant may direct him in his sucking, but should never be fastened up in the pen. It is expedient that the pens be kept constantly well littered with the cleanest straw, a proportion of which should be thrown in to every day; cleanliness being a most essential article in the fattening of every animal, and more necessary to any than to a calf, which, being in a small space, concentrates the ill effects of an over-laying on his accumulated dung, which of all animals is the most offensive and of a quality highly septic. As the calves are yeaned, they are to be taken into the pens, and suckled by their own dams, which at first will yield a far greater quantity of milk than is necessary for their offspring, so that another calf may be suckled thereon; or the cow may be milked, and the cream be reserved for butter, or applied to any other use that the owner may think proper. As the calf increases in size, it will require a larger quantity of milk; but whilst calves are young, one good cow will yield a noble supply for two; and when the whole produce is demanded for one calf, which is the case in a further stage of growth, and these two cows will abundantly supply the three calves with milk till the oldest is fit for the butcher; after which, if necessary, a fresh suckler may be brought in, and the business be carried on progressively by keeping the house constantly supplied with calves, so that the whole milk may be sucked, as the dairy and the fattening of calves by sucking cannot be conveniently united.

6545. The only advantage which sucking can have, over giving calves milk to drink, is, that the action of sucking induces a greater secretion of saliva, which, by promoting digestion and digestion, fattening of the young animal, cannot be doubted; but the secretion of that fluid may be likewise promoted, by placing an artificial teat in the mouth of the calf, and giving it the milk daily and at the natural temperature. In the dairy districts of Scotland, the dairy maid puts one of her fingers into the mouth of the calf, for the purpose of a test, and if the pustule is found to be tender, and these two cows will abundantly supply the three calves with milk till the oldest is fit for the butcher; after which, if necessary, a fresh suckler may be brought in, and the business be carried on progressively by keeping the house constantly supplied with calves, so that the whole milk may be sucked, as the dairy and the fattening of calves by sucking cannot be conveniently united.

6546. Young calves, when permitted to suck their fill, are often seized with a lax or scouring: to prevent which, the calves for the first fortnight or three weeks may be stinted in their allowance of milk, but not so much that they do not put on flesh or want of milk. But after this age they should be allowed to suck as long as they choose; and every means ought to be made use of to increase their appetite, and render them more eager after their food. Milk may be given for this purpose, as well as for giving to them a delicate white crust, which, with a cup of milk, and a little ground nutmeg, will be a very good and nourishing substitute, and is a substitute which their dams are accustomed to give them in winter; and of course, their young and delicate constitution will not allow of the same aliment. On the other hand, a little milk sprinkled in the trough will likewise act as a stimulus to the appetite; besides which, it is a common practice with some people to eran their calves with balls compounded of flour, pounded milk, and milk, with the addition of a small quantity of common gin. Of these balls they give
two, about the size of a walnut, once a day, or oftener, to each calf. These balls, being very nutritious, in some degree supply the place of milk, and at the same time prevent the sweetish mixture of other food, composing them to sleep, increases their disposition to fatten; but where milk can be had in sufficient abundance, it is never worth while to have recourse to these factitious aids. When the demands of the calf, however, are beyond the ability of the cow, these balls come seasonable. Be it observed, that all these measures may be taken with facility; when 10 pounds of calves should be changed, whenever the cows are found to be deficient in this particular; and in the winter time, such food as is of a succulent nature, as grains, turnips, &c., should be always at hand to supply the want of grass; and these, with a due allowance of the sweetest hay, should be their constant alliment during the winter, that the cows are confined to the yard.

6847. The prices of sucking calves vary according to the goodness of the young animal, and the time of year wherein the purchase is made. In general, sucklers fetch the largest price in summer, when veal sells the cheapest; and the reason of this arises from the smaller number to be met with at that time than in the spring. When calves are slaughtered at six weeks or two months old, the veal is seldom of a good colour; neither has the flesh of these young calves a taste equal to that of animals suffered to live a few weeks longer. To attain a colour and taste superior, it is necessary that they be pleased with turnips, and managed as before directed, till they arrive at the age of eight or ten weeks, according to the season of the year, the more or less kindly state of the calf, the particular demand of the market, or other accidental circumstances. In the summer season, it may be proper to dispose of them at an earlier time, and to winter them away on any account; for in hot, warm weather, but likewise because of the increased demand for small veal, which is then most saleable. During the last three or four weeks, blood should frequently be drawn from the calf, which will be a likely measure; for the difference between felling and thinning a veal has known cattle, sheep, and swine kept for months, and fed with a view to fattening them, without their gaining a pound of meat.

6852. The fattening of cattle demands considerable and constant attention, and the grand object is to fatten quickly. An animal when in a state of rearing may be considered as a veal; open at both ends, in which the supply and the waste being nearly equal it can never be filled: fattening an animal may be considered as an attempt to fill the vessel, and this can only be done by an excess of supply. The waste is the same as before, this excess must be great; if it is not so, the vessel may be filled to a greater height than before without ever becoming full. An important hint might be taken from this simile by many farmers, who spend theire time between feeding and thinning. We have known cattle, sheep, and swine kept for months, and fed with a view to fattening them, without their gaining a pound of meat.

6853. The food on which cattle is fattened in summer is grass, commonly on pastures, but, in a few instances, cut and consumed in feeding-houses or fold-yards: in winter by far the greater number are fattened on turnips, along with hay or straw; oil-cake, car, potatoes, and other articles of food, are used occasionally, and in particular districts, oil-cake chiefly for feeding the larger animals: but few, comparatively, are fattened on any of these without the addition of turnips of one or other of the varieties generally cultivated. The number of cattle are always above the number of young feeding on the same land, the tilling from corn; a source of supply, the frequent interruption of which has been much felt in those circumstances where the soil does not permit the extensive cultivation of turnips. It is seldom or never the practice of the best managers to fatten cattle with roots or other winter food on the field, during that season, contenting themselves with houses or fold-yards, where they can be sheltered, regularly fed, not liable to be disturbed, and sheltered from the inclemency of the weather, and where the manure they make is an object of very considerable importance, and of much greater value than if it were dropped at random over a winter field.

6854. The age at which cattle are evidently catted depends upon the manner in which they have been reared; upon the proprieties of the breed in regard to a propensity to fatten earlier or later in life; and on the circumstances of their being employed in breeding, in labour, for the dairy, or reared solely for the butcher. In the latter case, the most important breeds are fit for the market in three years old, and very few of any large breed are kept more than a year longer. As to cows and working oxen, the age of fattening must necessarily be more indefinite; in most instances the latter are put to feed after working them the seventh year of their age. In the markets, the state of cattle are fatted on pastures, though sometimes finished off on a few weeks' turnips; and that large cattle, at least in the north, are chiefly fattened in stalls or fold-yards, by means of turnips, and the other articles before mentioned.

6855. Stall-feeding is the most common, and, when judiciously conducted, probably the most eligible method, in regard to the cattle themselves, the economy of food, and the expense of farm buildings. The small shed and fold-yard, called a hammel (2561), are used only for the larger breeds; but they do not
well calculated for an extensive system of fattening by those who do not breed, but purchase stock every year. (See Part IV.)

566. The two great points in feeding animals to proof, according to the author of the Farmer's Calendar, are, regularity, and a particular care of the weaker individuals. On the latter account there ought ever to be plenty of trough or rack room, the stronger herd generally may not feed in it, which is very common case the weaker, are not only thinly clad over, but are also, from their spirits, less, than which there cannot be a more unfavourable state for thriving; besides, these are ever compelled to shift with the worst part of the meat. This domineering spirit is so remarkably prevalent amongst master-beasts, that he has bountifully observed from the practice, without even neglecting their own provender for the sake of driving the inferior from them. This is, much oftener than suspected, the chief reason of that difference so visible in a lot of beasts, after a winter's keep. It is likewise, he says, a very common and very serious fault, to see a herd of cows, that are not fattened and wended in a dozen places, merely from the inattention of the owner, and the neglect of tipping the horns of those but. The weaker animals should be withdrawn and fed apart; and, in crib-feeding in the yard, it is a good method to tie up the master-beasts at their meals.

567. Fattening cattle. Donaldson observes, that it is usually put to pasture in May or June, according to the season and situation in regard to climate. The period necessary for fattening an ox for the butcher depends on several circumstances; as, the condition he was in when put to grass, the nature of the pasture, and ordinary and other winters. In three months, however, the bulk of the fat will be obtained.

568. The method of fattening cattle with oil-cake, corn, cut straw, &c. is practised in many of the English counties, with a degree of success sufficient to warrant farmers in other parts of the island to follow the same practice.

569. It is usual to have all the beef cattle fattened to the same degree that the dairy is fattened in the same way. It is unique, however, that the fat done in the first is fattened to raise the latter. It is broken in a large mortar, or, in the fruit districts, in a cider-mill, is about half a peck per day, one half in the morning, and the other in the evening; to which is added hay, and in some cases ground corn, that oats or barley of inferior quality, and cut straw, provisionally "chaff." As bullocks fatten in a manner yet regularly six, meals a day, it is sufficiently evident that, although it may be, upon the whole, an expensive mode of fattening, yet it must be both expeditious and effectual.

569. 1. Book's establishment for fattening cattle at Bredfield is one of the most extensive in the neighborhood of London. It was formed for the purpose of consuming on the spot the grass and wash of the extensive distillery of that family. The building is 210 feet long, and 130 feet wide, and calculated to contain 600 head of cattle. It cost 6000L. The side walls are about 10 feet high, with 20 windows on each side, and 5 windows at each end, not glazed, and a few glazed skylights in the roof. The roof forms one ridge, and the centre part of it affords space for an ample hay loft; it is supported by cast-iron and wooden pillars, so numerous as to have the appearance, on first entrance, of a forest of columns. A passage of six feet, the centre of which is paved with plates of cast-iron, is contained in the whole building, and between every two rows of cows of cattle are passages of the same width and description. The bulk of the cattle is kept in stalls seven feet and a half wide; and the space from the manger to the wall is open. In a second section of the building the mangers have an inclination to one end, and are, under-graded by the same inclination, in which the liquid from the gutters is conveyed through pipes in the floor. There is a common manger which extends the whole length of each row of cows, and another which is in the partition wall. The portion of this manger contained in every double stall has a second portion, in the partition wall, over the whole depth of the manger belonging to each stall, is put the grasses, or other sold food; the common manger being for the reception of the wash, or other liquid food or drink. The immense quantity of wash which is produced by the manufacture in a citizen or tank or rank of these levels of mangers, and in a different part of the premises, but pipes from this tank are conducted under the same surface and commence at the middle of them, so that by turning a cock the whole of the cattle in any one of the buildings can be supplied. This method of washing cattle is, in the article serves both as food and drink, as it contains the finer particles of the ground-stall, and the greater part of the barley meal used in the washing process. The grains are kept in deep pits about twelve feet square, and ten or twelve feet deep, somewhat narrower at bottom than at top, lined with brick set in cement; and when the grains are broken in, and raised like the ridge of a causeway, the whole area is covered with straw. The cattle in the wash, and protected from the weather. Little or no litter is used, and even the straw is employed in the washing process. Oil-cake is used, but not always; it being found that rough clover chaff, mixed with the grain and wash will fence to any extent.

569. 2. This building, though erected at great expense, is very unprofitable, and far from economical. It is much too cold in winter from the openness of the roof, and, externally, very un-pleasing to the eye. It has been said to reduce the result of the cattle extremely distiguished by seemingly insumerable posts, three fourths of which are of oak only. The roof is supported by cast-iron columns, and the roof is of wood. A long and narrow cow does not produce the same, though it is equally useful, and much handsomer structure might have been erected. It has never paid a profit to its owners, who, if they could sell the wash and grains at the present market price, calculate that their profits would be considerably greater than by consuming it on the premises.

571. Milk cows are kept for the manufacture of butter and cheese, for the sucking of calves for the butcher, and for the immediate use of the milk.

572. The kind of cow used by the dairyists who supply the London market is chiefly the Holstein, a very active and hardy breed, well known for its white and red colors. They are generally kept there and in the counties of Yorkshire and Durham; but in part in most counties. The Edinburgh dairies are supplied by short-horned cows from Roxburghshire, and other pastoral districts in the south of Scotland. For private dairies, the variety breed in Ayr is chiefly used. For large districts, the difference, as giving a rich milk and large proportion of butter; and the cheese made from the milk of this breed, known as Dunlop, is decidedly celebrated. In Lancashire, the native long-horned breed is said to be the best. In the county, to obtain the general preference; but in Hodgson's dairy at Caton, in the same district, it was found that a short-horned cow, under an average of the month, will yield nine quarts of milk in the day, and four and a half pounds of butter in the week; and a long-horned cow gives eight quarts of milk in the day, and four pounds of butter in the week, for the same time. The milk of this breed has constantly the same kind of food; and, in order to have the clear result, the quantity of food consumed by each cow in the different breeds should have been fully ascertained.

The production of milk and butter is on the side of the short.
herned sort; but it is not ascertained whether the neat balance is in favour of the short or long-horned.

883. Where butter is the principal object, such cows should always be chosen as are known to afford the best milk land, and in the largest quantity, of whatever breed they may be. But the weight of butter to be made from a given quantity of milk must depend on the fatness of the milk, as shown by its size and goodness of the breasts; the kind and quantity of the food; and the distance of time from calving. As to the first, it need scarcely be mentioned that a large cow will give greater store of milk than one of a smaller size; though it is sometimes a matter of contest as to whether it is better to have large or small cows, for the disposition of the udder, those who would wish to profit by a dairy ought to provide for their cows hay of a superior goodness, to be given them in the depth of winter, and this in an unlimited degree, that they may always feed them perfectly satisfied; and, in consequence of the weather being wet, when the weather is wet, when the weather is not, with an abundance of fine grasses or low meadows or good grounds, where they may feed on such green vegetables as are present, which is far preferable to the practice of confining them the whole day on dry meat, will enable them to yield greater plenty of milk, and will give a fine yellow colour to the butter even in the winter season.

884. In the vales of Buckinghamshire and Oxfordshire, very great numbers of cows are kept for the purpose of butter. These fertile lands maintain a breed of large cows, which yield great store of milk; so that it is an uncommon circumstance to find one farmer keeping a herd of fifty or sixty, and to collect a quantity of cream sufficient to fill a barrel-churn of sixty gallons in a week. The butter made from this cream is sold by the farmer or dairyman to persons who make it their business to purchase this article at a stated price from Michaelmas to Lady-day, and at an inferior rate from Lady-day to Michaelmas. The butter is then sent to London every week in waggonets. It is consigned to the dealers, who retail it to the consumer; and no small profit from this traffic accrues to the waggoner and the butter-merchant. This butter is mostly made up in lumps two pounds each, and for that reason it has obtained the name of lump-butter. Its flavour is peculiarly sweet and agreeable, and it is much in demand for this use. As to the price, and for this intrinsic merit would in vain be sought for in butter made from ordinary pastures, how great soever may be the skill of the dairy-woman. Though the grass should be absolutely equal, the cows of the same breed, and the cream in like abundance, yet would a decided preference be given to the vale-fed cows; for the same, or even a much finer milk, being given to cows, so will cows give a large store of better milk, and that of a more nutritious quality, when fed on deep fertile meadows, than if depastured on those of inferior goodness.

885. Butter has long been held in the highest estimation; and great quantities are manufactured and sold in Cambridgeshire and the adjoining counties. The Cambridge butter is sent in small pans; it has an additional quantity of salt mixed with it, to insure its keeping for ten days or a fortnight; and is generally prepared from any rancid or unwholesome butter. Yorkshire butter is rich and fertile, likewise supply large quantities of butter, which is salted and put into tubs for the southern markets.

886. Where cheese is the principal object, the management in respect to the cows must be the same.

887. Where milk is the object is the suckling of calves, the farmer should provide himself with a breed of cows suited to the quality of his land. Where the farm abounds with fertile pastures, watered with wholesome streams, and not far distant from the yard, so that the cows may be turned immediately out of the sucking house upon their feed, the benefit will be in every respect superior to the cows on the farm, or where the green land is in a small proportion to the ploughed; for, in this latter case, the cows must depend for their sustenance chiefly on artificial food; such as clover, rye-grass, turnips, and other roots and herbage.

888. The cow-house should be of a size adapted to the number of the beasts. Each cow should be driven into the house at suckling-time, and her head confined in a proper manner, having some fodder lying constantly before her, and a space left between every beast. When they become accustomed to this arrangement, they will without any trouble come into the places destined for them, when the calves may be suckled with the greatest ease and facility.

889. The time cows should become dry before their calving is not agreed on, some contending that they may be milked almost to the time of their dropping the calf without injury; while others maintain that it is better to let the cows dry for two weeks, and then to be laid for three days before they drop themselves and their calves. It is probable that much in this business must depend on the manner in which they are kept; as when well fed they may be continued in milk till within a week or two of their calving, without suffering any injury to themselves from it; but injury will be done to them if they are allowed to run dry for a month, six weeks, or more, according to their condition, in order to their more fully recruiting their strength. It appears impossible, but that the longer the milking is continued, the more free the cows will be from indurations and other afections of the udder; which is a circumstance deserving of attention. Where only one or two cows are kept for the supply of a family, it is likewise known that by feeding them they may be continued in milk without any bad consequences till nearly the time of calving.

890. Cows sometimes, slip their calves before they are sufficiently grown. Where this occurs, it is essentially necessary to remove such cows immediately from the cow-yards, or from mixing with the other cattle, for a few days. But where cows are much subject to such accidents, it is the best method to get them off by that time of their dropping the calf without injury; otherwise they will often slip their calves at once and afterwards.

891. The herd of cows is kept in good condition, as where they are ever suffered to become very lean, and that in the winter season, it is impossible that they can be brought to afford a large quantity of milk, by getting them into perfect condition in the summer months. Where cows are lean at the period of calving, it is manifest that they will be incapable of giving any thing near the proportion of milk that they would have done if they had been supported in proper condition during the winter. Food of the most nourishing and succulent kind should therefore be regularly given in suitable proportions in the cold inclement months, that the cows should be kept as fat as possible, as such a state is preferable to their being defended by counting and other means; but this is a practice which, though useful in making them yield their milk more freely, can perhaps seldom be advantageously employed on an extensive scale.

892. The herd of cows is kept in good condition, as where they are ever suffered to become very lean, and that in the winter season, it is impossible that they can be brought to afford a large quantity of milk, by getting them into perfect condition in the summer months. Where cows are lean at the period of calving, it is manifest that they will be incapable of giving any thing near the proportion of milk that they would have done if they had been supported in proper condition during the winter. Food of the most nourishing and succulent kind should therefore be regularly given in suitable proportions in the cold inclement months, that the cows should be kept as fat as possible, as such a state is preferable to their being defended by counting and other means; but this is a practice which, though useful in making them yield their milk more freely, can perhaps seldom be advantageously employed on an extensive scale.
of pestation is accomplished, assumes, in some degree, the appearance of milk, and may be drawn from the cows' udders during their browsing at the time the milk is being produced. This part is more than ordinarily large and distended. Heifers are said to spring sooner at bearing, and old cows at the under supporting of the stomach; and where this happens, they should never be continued long in the herd, as being unlikely to yield any considerable degree of profit to their owners.

8678. Cows are capable of being allowed to be lodged at night in a large convenient out-house, or some other place, for a week or two previously to calving, as it may be the means of saving the life of the calf, and perhaps that of its dam: for, when a calf drops in the yard or field under such circumstances, the vitality of the weather is very great, and it may happen that the cold of the air and the inclement of the weather suffers to be felt out of any cold water. By this immediate treatment we shall mostly recover in a few days; but should the disorderedang about her, balls composed of aromatic cordial substances may be given.

The calving is over, and will generally continue in a good milking state till ten years old or upwards; but this depends greatly on the constitution of the animal, some cows, like other animals, exhibiting marks of old age much earlier than others.

8679. Cows of large size yield great store of milk when turnet on pastures where the grass is in sufficient abundance, or feed with as much food as the cow will consume; much food produces much towards the nutrition of the creature, and enables her to give large quantities of milk, such as turnips, grass, garden vegetables, &c. But as these large cows require a more ample provision than would fall to their share on the generality of farms, it would seem that they could not be kept by those farmers whose land is not of the most fertile kind; for, on ordinary small, a cow will yield a fair profit than of the of the

8680. For feeding of stoned cows, the following directions are given to the cow-feeder in an improved dairy establishment near Farthing, in Surrey:—"Go to the cow stall at seven o'clock in the morning, when the cows are just milked; give each cow a bucket of water; then the field beet, carrots, turnips, or potatoes cut; at seven o'clock, the hour the dairy-maid comes to milk them, give them a little corn, and let every one of them is all milked. If any cow refuses hay, give her something she will eat, such as grains, carrots, &c., during the time she is milking, as it is absolutely necessary the cow should feed whilst milking. As soon as the dairy-maid has finished milking, turn the cows into the manger ground, and let there be plenty of fresh water in the troughs; at nine o'clock give each cow three gallons of a mixture composed of eight gallons of fresh and four gallons of bran or pollard; when they have eaten that, put some hay, and they will eat three or four gallons of the mixture as before; if any cows look for more, give her another gallon; on the contrary, if she will not eat what you give her, let it out of the manger, never at one time letting a cow have more than she will eat up clean. Mind and keep your mangers clean, that they do not get sour. At two o'clock give each cow half a bushel of carrots, field beet, or turnips; look the turnips, &c. over well before you give them to the cows, as rotten turnip, &c. will give a bad taste to the milk, and most likely spoil a whole dairy of butter. At four o'clock put the cows into the stall to be milked; feed them on hay, as you did at milking time in the morning, ever keep your mangers clean and do not feed on something, at six o'clock give each cow three gallons of the mixture as before. Each one up at eight o'clock. Twice in a week put into each cow's feed, at noon, a quart of milk dust."

8681. Directions to the dairy-maid:—"Go to the cow stall at seven o'clock; take with you cold water and feed the cows before milking; only wash the floor clean with water, vinegar, and a little compost; this is winter and summer, as it braces, and repels heat. Keep your hands and arms clean. Milk each cow as dry as you can, morning and evening; and when you have milked each cow, as you suppose, dry, begin again and see if you have not milked it too much; for the milk in failing in its milk is from negligence in not milking each cow, particularly at the time the calf is taken to cow, and the cow

Suffer no one to milk a cow but yourself, and have no gossiping in the stall. Every Saturday night give in an exact account of the quantity of milk each cow has given in the week." "Farm. Mag. vol. xvi. p. 314.

8682. Harley's dairy establishment at Glasgow has been celebrated since 1813. The object of the proposer, who is engaged in various extensive concerns, is to supply the public with new milk free from adulteration, and to have the cow-house, cows, and milk kept in a more cleanly state than by the usual mode.

8683. Harley's cow-house is fitted up upon a new construction. The cattle stand in rows, twelve in row, across the house, head and tail opposite each other, and the straw is placed behind the stalls for cleaning, and one in front of each om. In front of each stall is a small partition, upon which the water is dispensed, which lifts up when giving the soft food and cleaning the cribs, and is lowered for the cows to eat from. There are troughs for washing the cribs, collecting the urine, ventilating the house, &c. The cows are furnished with the necessary apparatus, which may be summed up in the following items:—The cow: the preservation of the cattle; the preservation of the timber; the damaged danger; the general cleanliness of the house, &c. The cleanliness of the cow-house can be produced, so as to keep the cattle comfortable in the hottest weather. The milk is sent from the cow-house also the milk is from prevention in not milking each cow, particularly at the time the calf is taken to cow, and the cow

Suffer no one to milk a cow but yourself, and have no gossiping in the stall. Every Saturday night give in an exact account of the quantity of milk each cow has given in the week." "Farm. Mag. vol. xvi. p. 314.

8684. Harley's dairy establishment at Glasgow has been celebrated since 1813. The object of the proposer, who is engaged in various extensive concerns, is to supply the public with new milk free from adulteration, and to have the cow-house, cows, and milk kept in a more cleanly state than by the usual mode.

8685. Harley's cow-house is fitted up upon a new construction. The cattle stand in rows, twelve in row, across the house, head and tail opposite each other, and the straw is placed behind the stalls for cleaning, and one in front of each om. In front of each stall is a small partition, upon which the water is dispensed, which lifts up when giving the soft food and cleaning the cribs, and is lowered for the cows to eat from. There are troughs for washing the cribs, collecting the urine, ventilating the house, &c. The cows are furnished with the necessary apparatus, which may be summed up in the following items:—The cow: the preservation of the cattle; the preservation of the timber; the damaged danger; the general cleanliness of the house, &c. The cleanliness of the cow-house can be produced, so as to keep the cattle comfortable in the hottest weather. The milk is sent from the cow-house also the milk is from prevention in not milking each cow, particularly at the time the calf is taken to cow, and the cow

Suffer no one to milk a cow but yourself, and have no gossiping in the stall. Every Saturday night give in an exact account of the quantity of milk each cow has given in the week." "Farm. Mag. vol. xvi. p. 314.

8686. The stock of cows for some time back has been 150, averaging eleven milk cows, and 40, averaging 14, or 210, including 35. The system is to have the stock gradually increase in numbers and quality, and depend much upon the kind of food. Harley gives a decided preference to the milk of the Holstein breed. He also states that he bought chiefly at country fairs, either newly calved, or a few weeks before calving, and never turned out till they go to the butcher.

8687. The food of the cows during summer consists of cut grass and green barley mixed with old hay, and during winter Harley uses a good many turnips and potatoes, all of which are strained and washed before they are given. He also uses both grass and distiller's wash, when these can be got.

8688. When there is a frost, or when they are disturbed, or when milked, put the milk in the milk-house till next day, when the milked milk is sold at half price, and the cream sold at 1s. 6d. per quart. When the milked milk is put in a churn, and the cream into butter once a week or fortnight.

8689. A system is also adopted for the times of feeding, milkling, every cow, cleaning the house, &c. Each person has a key to a hair of the cow, and each cow twice a day, and 2 mop and brush for the house, which is washed and burned twice a day.

8690. The cleanly state of the cow-house and milk makes it a treat for visitors to see the establishment; and the way the vessels and milk-house are kept he; some people find of milk which formerly were disgusted at it, from the manner in which many town dairies are conducted.
6591. The advantage of irrigating grass leads with the cows' udders above exceeds belief. Last season some small fields, each with two or three hundred milk cows, were divided into sections six inches in length at each cutting, and the sward very thick. The consequent poor quality of milk was at once perceived as being a great waste of time and money, and the grass was prepared for forwarding to market. It is estimated that a square foot of pasture that leads with the cows' udders above brings on the average a quarter of a cent per gallon of milk, and that every cent of this is easily saved by proper attention to the business.
The management of Rhode’s dairy is committed to three persons—A clerk, who keeps the books, collects debts, pays and receives; a man, who superintends the feeding and the treatment of the stock, and has the general care of the premises; and a dairy-woman, who sees the milk measured to the dealers, and superintends the dairy, and is employed in cleaning and selling by retail.

The dairy establishment is situated at Edgewater, and covers a number of acres. The cows vary in amount from 100 to 200, and are kept within a yard, furnished with shelter from 3000 to 5000 head of cattle, and these sheds are accordingly appropriated to taking in cattle for the night, prevalent in the neighbouring fields. We shall only notice those particulars in which this establishment differs from the one we have described. As far as possible, the cows are kept in the same manner, with the exception of not receiving any salt and only being fed on turnips and potatoes. They are turned out once a day to drink from troughs in the morning and evening. The milk is churned from two o’clock in the afternoon till about three o’clock in the next day. From this hour till noon of the next day they are in the cow-houses for the purpose of being milked. The cows are kept in the same order as in Mr. Laxey’s establishment. Those which become barren are fattened in the same manner on grains, oil-cake, and, what is rather uncommon, beets. This is believed to be a common practice, and when reduced to a pulp, let out by tubs into large wooden cisterns, where it is mixed with cattle-chaff, roughly cut, and sometimes with grain, and afterwards given to the cattle. Those cows which are good milkers are allowed to take the bull, for which purpose eight bulls are kept. The usual number of males is four; the calves are sold in Smithfield, when only a few days old, to those whose business it is to take them to the country and feed them for the butcher. Mr. Laxey has an extensive farm at Howlaies, another at Enfield, and one at Clayton; at one or other of these places the cows are fattened. The hair of the tails is kept short to avoid the risk of dripping the milk, and to facilitate the cleanliness of the udders. The fattening cows stand their hind feet on planks, laid as part of the pavement, the latter consisting of rather small shingle. The wood with which they are boarded, the comers, are fattened with around lined and cleaned. The establishment is thus admirably adapted for this kind of business, and is peculiarly well made, and as the barns are properly insulated, and there is no farm belonging to the establishment, when a cow in calf becomes three months old, it is sent to the country, till near her calving time. To tender a cow dry, it is only necessary to feed her half a pound of salt in her food. The quantity of salt given here daily with the grains is not much more than an ounce a day, on account of its drying property. Mannings, and the weight of the milk, gives it to the establishment to Yorkshire; but this is found not to pay; and of so little importance is the matter, that no concern is paid much attention to it. A cow has, in such a case, much as possible of the fluid part is discharged by the common sewer; and the present proprietor contemplates to compress the more consistent material into small squares called pasts for feed. By a hydraulic press we have no doubt that a two-horse press can be constructed to any circumstance, reduced to the size of a cubic foot. The cows in this establishment, as in all others, are very well fed. The milk is given is chiefly laid about their fore legs, and in consequence the other parts of the animal, for which latter purpose a great number of beet cutters, as in Holland and Germany, are always watery and dirty.

SUBJECT 8. Working of Horned Cattle.

The working of Horned Cattle.

The argument for and against the working of oxen have been already stated. (1828.) Though horned cattle are gradually disappearing as beasts of labour, it is probable they will in many places be occasionally used as substitute for horses, or to get up one or two additional teams on extraordinary occasions. The usual objection to the habitual use of horned cattle is that they are less easily kept as the ox, at any age, and in most countries, where they are used in labour, they are never handled till harnessed and put in the plough, or to drag a tree. This is the case both in Devonshire and

which its present name is derived, is now the property of Mr. Willtorfte. It stands on less than an acre of ground, and is well arranged. It is calculated for 500 cows, most of which are in fine, but some are fattening. The cow-houses are in parallel ranges twenty-four feet wide, with twelve cows to each, a shed 300 feet long, without stables, with gutter in the centre, and no raised foot-path there; it being found that they are very much injured by the dust and ashes, so smudgy, when turned out upon any occasion. It is true, these conclusions are, for cows here, as in Mesra’s establishment, that never undertake to do more than their daily work, till they are removed to the fattening sheds, or till they are taken out to pasture, and so their excreta are kept till calving time. A cow so treated seldom produces more than two calves, whereas, in England, the number of calves is nearly four; they are in the cow-houses for the purpose of being milked. The cows are kept in the same order as in Mr. Laxey’s establishment. Those which become barren are fattened in the same manner on grains, oil-cake, and, what is rather uncommon, beets. This is believed to be a common practice, and when reduced to a pulp, let out by tubs into large wooden cisterns, where it is mixed with cattle-chaff, roughly cut, and sometimes with grain, and afterwards given to the cattle. Those cows which are good milkers are allowed to take the bull, for which purpose eight bulls are kept. The usual number of males is four; the calves are sold in Smithfield, when only a few days old, to those whose business it is to take them to the country and feed them for the butcher. Mr. Laxey has an extensive farm at Howlaies, another at Enfield, and one at Clayton; at one or other of these places the cows are fattened. The hair of the tails is kept short to avoid the risk of dripping the milk, and to facilitate the cleanliness of the udders. The fattening cows stand their hind feet on planks, laid as part of the pavement, the latter consisting of rather small shingle. The wood with which they are boarded, the comers, are fattened with around lined and cleaned. The establishment is thus admirably adapted for this kind of business, and is peculiarly well made, and as the barns are properly insulated, and there is no farm belonging to the establishment, when a cow in calf becomes three months old, it is sent to the country, till near her calving time. To tender a cow dry, it is only necessary to feed her half a pound of salt in her food. The quantity of salt given here daily with the grains is not much more than an ounce a day, on account of its drying property. Mannings, and the weight of the milk, gives it to the establishment to Yorkshire; but this is found not to pay; and of so little importance is the matter, that no concern is paid much attention to it. A cow has, in such a case, much as possible of the fluid part is discharged by the common sewer; and the present proprietor contemplates to compress the more consistent material into small squares called pasts for feed. By a hydraulic press we have no doubt that a two-horse press can be constructed to any circumstance, reduced to the size of a cubic foot. The cows in this establishment, as in all others, are very well fed. The milk is given is chiefly laid about their fore legs, and in consequence the other parts of the animal, for which latter purpose a great number of beet cutters, as in Holland and Germany, are always watery and dirty.
Herefordshire, and as they are only worked a few years it does not seem desirable to be at any great expense in their training. The Roman practice, in this particular, may deserve imitation. (293)

909. Working oxen when kept in a house are generally confined to their places by the same sort of fastening used for cows, (fig. 865), in which their neck has free play between two upright spars; but in some establishments a ring of a particular description (fig. 896) is used, to which they are tied by a halter attached to a head strap or stay-tree. The ring is generally screwed into the front of the manger or eating trough. The cattle fastening used in Devonshire is a wooden bow put on their necks and fastened to a yard or field post. The bow consists of two pieces: the yoke, which has two slits terminating in round holes; and the bow, which is made of split ash, and has a knot at each end. These knots being put through the round holes, the elasticity of the bow forces it along the slit and prevents it from returning.

911. Harness for labouring cattle is of three kinds: that for bearing as saddles some sorts of oxen yokes; that for drawing or pushing, as tracés, brochins of saddles, &c.; and that for guiding the animals, as bridles, halters, reins, &c. These articles are of considerable expense, but when taken care of, kept dry, and the iron joints and leathers oiled occasionally, they will last a long time. In making all harness for beasts of labour great care ought to be taken to avoid superfluous materials which only encumber, and ornament which only add to the expense. The London harness is much too heavy for agricultural purposes; that of Berwick or Newcastle is much more light and sufficiently strong.

912. The most approved kind of harness for the ox is little different from that of the horse, except in the shape of the collar. In many places however, and especially on the Continent, the ox draws solely by the withers, by means of what is called a yoke and bow. (fig. 867.)

913. The shoeing of oxen is a practice which is yet far from being performed in a perfect manner. Clark says, that in many parts of France, where the ox is used for draught, it is sometimes necessary to employ eight shoes, one under each nail; or four, one under each external nail; and sometimes only two, one under the external nail of each fore foot. In this country two pieces or shoes to each foot are generally made use of, being mostly fixed on, especially in the northern districts, with three or four large-headed nails to each shoe, which are fitted on in a similar manner to those of the horse. But, as the shoes of these animals from the smallness of the pieces are so liable to break, it has been suggested to have them shod with whole shoes, in the manner of the horse; but how far this practice would answer, must depend upon future trials. As there is much trouble in the shoeing

break, it has been suggested to have them shod with whole shoes, in the manner of the horse; but how far this practice would answer, must depend upon future trials. As there is much trouble in the shoeing

868

of oxen, from the necessity for casting them each time, it has been found requisite to have recourse to contrivances for shoeing them standing (fig. 888).

869. An ox shoe (fig. 867) consists of a flat piece of iron, with five or six stamp holes on the outward edge to receive the nails; at the toe is a projection of some inches, which, passing in the cleft of the foot, is bent over the heel, so as to keep the shoe in its proper place. This projection is not, however, employed in the general practice of making these shoes.

870. The age at which an ox may be worked is from two and a half to three and a half years. Some begin at two, but it ought to be for very light operations, and such as are not of long duration. The period to which the ox is worked varies from his fifth to his tenth year.

871. Parkinson's father used to make up occasionally an ox team for the plough of four oxen and one horse as a leader, which he found did about two thirds of the labour of two horses. There are, he says, great objections to ox teams in the plough. He has, however found them useful in some sorts of farm-work, from their slow, steady pace; as in scarifying, leading dung, &c., as the work suits them from its being easy, and having a great deal of standing: they are, says he, much more cheaply kept than horses and eat straw in the winter, and are valuable for making dung. He never saw this practice injure their health. They may be worked from two till five years old, without any loss of time, as they grow to that age, and are then both larger and better beasts than three-year-old steers. He therefore recommends ox-teams for leading dung and the other odd jobs; but not to plough and harrow. If they are worked to the house they, with care, the horse, for all the perfection in other one else, prefers the Devon breed, which most cultivators consider the quickest walkers in England. When horned cattle are only worked occasionally, whatever sort of animals are on the farm, whether bullocks, cows, or oxen, of good or bad breed, will necessarily be employed.

872. The food of horned cattle employed in labour must be substantial. It is a great mistake to suppose they can work on straw alone. Unless they have roots added to straw in winter, and green food in summer, it will be an idle attempt to harness animals so nourished. The best and indeed the only way is to feed them well with straw, coarse hay, roots, green herbage, or pasturage, as the season and other circumstances may indicate.

921. The general structure of the bull and cow presents some peculiarities when compared with the horse, but they will be taken as the subject of comparison with the ox, as an animal machine, displays less complexity of structure than the horse; but the principal differences between the two will be found to arise from the evident intention of nature to bound the locomotion of horned cattle: the limbs of the ox are therefore not found favourable to speed; nor does his general mass bear any resemblance to the corporeal compositions of the other domesticated animals. The ox, in regard to the speed, as it regards quick motion, by the powerful muscles he evidently possesses; for strength alone will not produce speed.

922. The skeleton of the ox is formed under the above view; and though the number of his bones differs little from that of the horse, the general form differs materially; — the frontal, the occipital, and indeed most of the bones of the skull are broad and extended, while to the former are appended the horns. These, as we have seen (1562), partake of the nature of true bone, placed within a membranous envelopment, for the purposes of the manufacture of the rump and tail. The external matter forming the surface, or cuticle; the grass, cropped into a tuft by means of the tongue, is cut off by the under nipples; whereas in the horse it is nipped off by the approximation of both incisive teeth.

923. The bones of the ox consist of tubular bones of bone and form as in the horse; but from the diminished elevation of the head, and the peculiarity of attachment of the great suspensory ligament, the ox has no cervical vertebra. The dorsal vertebrae are thirteen, with spines processes, or withers less high. The lumbar vertebrae are six, and the sacral four; the coccyx or bones of the tail are indiscernible; numbers, from three to twenty-five. The pelvic bones in the ox are very large, the true pelvic girdle, or the two small, of the rump in cattle arises from the great rising of the spine of the ilium, and tuberosity of the ischium: the ribs are thirteen, eight of them true, and five false; and upon the former rest the sepatule, which do not materially differ from those of the horse.

924. The fore-limb bones are, the arm, and the fore-arm, which, as in the horse, is composed of the radius and ulna, and bears a general resemblance to that of the horse. The knee is composed of four bones in the first row, and four others that joint in the second row. The fore-limbs of the horse in complexity and elasticity: the same holds good with regard to the hook, where the bones entering its composition are no less numerous than in the horse. The canon or shank has no splint bone attached to it, but it is lower, and enlarges into two articular portions corresponding with the metacarpal before, and metatarsal behind; the distal end of the limb is doubled, those, that present, individually, a similarity of structure and design to the single hoof of the horse, but less developed; in the posterior part of each are appended two imperfect phalanges or claws, thus keeping a connection with the thigh.

925. The hind limbs present nothing remarkable, but preserve the same increased simplicity of structure with the fore.

926. The viscera of the chest offer no peculiarities from those of the horse to deserve notice; neither is the organ concerned in the organs considered.

927. The viscera of the belly of the ox have some specialities, the principal of which consist in the digestive organs, which differ in form, structure, and economy, in some essential particular, from the same in the horse.

928. The ox has four stomachs, in which formation the goat, sheep, camel, and deer participate. It is necessary that these animals should collect much herbage for their support; and as it would fatigue and keep them too long in motion to gather and masticate such a quantity at the same time, so a peculiar provision is made for them: they first hastily collect their food, pass it into a reservoir, and afterwards commence the mastication of it at their leisure.

929. The first stomach, rumen, or paunch, is a very large membranous and muscular bag, principally occupied with the food, and extends to full, and into which the unruminated food is received; consequently, it is the over-distention of this which occasions the malady called hoven; it is in this stomach also that the concretions called hair balls are found. This presents numerous processes to assist in the retention of the food.

930. The second stomach, called also reticulum, bonnet, or kingshood, would appear as a globular appendage to the paunch merely; it were not for its peculiarity of structure, which resembles the cells of the honeycomb, and which is well known to the eaters of tripe. The cesophagus, or gullet, enters at the juncture where the second is continued in the third stomach, a muscular tube along the line of junction between these two stomachs, which is thence continued into the mungs-pies. In the hornless ruminants, the second stomach is exclusively designed as a reservoir for water, and is capable of holding and preserving a vast quantity of it. A little of this water is passed up, as wanted, to be exchanged for mastication. In the ox, the water, as well as the masticated food, is retained, with only at long distances, this reservoir is peculiarly advantageous to the camel and dromedary; and the Arabian travellers, when famishing for water, save themselves frequently at the expense of their carcass, by rendering use of which, and taking out this stomach, they find a supply.

931. The third stomach is named after its foliated structure mungs-pies; there are about eighty or ninety of these sepia or folds, which are covered with cuticle, in common with the two former stomachs, by which some resemblance is kept up between the digestive process of the horse and ruminant by the comparative insensibility of these stomachs, they can also bear potent medicines, which would be destructive to the Carnivora. By this curious extension of surface, the ruminated food is applied and reduced to the sides of the bag, to be acted upon in its early stage of digestion.

932. The fourth stomach, called also the red bag, abomasum, falcus, and venriculus intestinus, is about two feet nine inches long in an ox, and resembles the simple digestive stomach of the Mammalia. It is in this stomach that the pultaceous mass of the chyme undergoes a more perfect assimilation by being mixed with the bile, which is wholly secreted in the liver and thence only produces rennet. The red bag, to increase its secreting surface, has likewise about nine longitudinal plicae to each side, with an intervening rugose structure.

933. Ruminatio, or chewing the cud, is the process whereby the ruminant animals have collected their food, and left in the paunch, with little or no mastication or expense of saliva, begins a new operation. The paunch being full, the animal is stimulated to seek rest and quiet, and he usually lies down. The paunch begins now to exert its extraordinary powers of separating a portion from the condensed into it in such a manner, that it undergoes complete mastication and mixing with the saliva. It is then again passed down the throat; but instead of again entering the first stomach, the muscular gullet forms itself into a tube, and carries it at once into the third stomach, where, having undergone a further change, it is passed into the red bag, or fourth stomach; to undergo further solution by means of the gastric fluid, preparatory to its being converted into nutrient under the name of chyle.

934. The intestines of the ox have not their divisions into great and small so well marked as in the horse. The wall of the rectum is extended in the form of a perfect separation of all the chylous particles. The intestines of the horse it has been shown (692) that much of the digestive as well as the operative process goes on; but the chymous mass is more broken down in the stomachs of a cow than by the united forces of the stomachs and intestines of the horse. Grass, containing leaves and organic matter, which to be minutely acted on to afford nutriment; and thus the well-fed horse, after having been sufficiently nourished, passes off dung containing much of the original principles of his farinaceous food, and which forms excellent manure; while that of the ox, becoming almost wholly decomposed and nearly feculent, is very inferior for that purpose.
PRACTICE and losenge but they and endemical malignant accompanied to the of the buli is more taper than that of the hearted and the vesicule seminaries is wanting, but have a small ligamentous bridge instead. The prostates are two.

Cattle are subject to some very dangerous diseases; but as their life is less artificial, and their structure less complex, they are not liable to the variety of ailments which affect the horse. The general pathology of the horse and the ox being little different, the fundamental rules for veterinary practice, and the requisite medicines, when not particularised, will be found in the Veterinary Pharmacopoeia, already given. (648).

Mild fever, pantas or pantásia. Cattle sometimes appear affected with heat, redness of the nostrils and eyelids; they refuse food, are dull, evacuate and stale with difficulty; and the urine is high coloured. These symptoms are often aggravated every other day, giving it an appearance of an intermittent affliction. The complaint is often brought on by over-driving in very hot weather, occasionally by pushing their fasting process too fast. If there be no appearance of malignancy, and the heaving be considerable, bleed, and give him an ounce of nitre in a drink night and morning; but unless the weather be cold do not house the animal.

Inflammatory fever is called, among farriers, cow-leeches, and graziers, by the various names of black quarter, joint felon, quarter evil, quarter ill, showing of blood, joint murrain, striking-in of the hogs, amputa, and sometimes felon-on. It is frequently attended with an eruption on the back, produced by a sudden change from low to very full keep. Over-driving has brought it on. No age is exempt from it, but the young often have it the most. Its inflammatory stage continues but a few days, and should be relieved by eye and nostril, and the nostrils are also red, and a slight mucus flows from them. The pulse is peculiarly quick; the animal is sometimes stupid, at others watchful, particularly at first; and in some instances irritable. The appetite is usually entirely lost at the end of the day, and the dung and urine either stop altogether, or the one is hard, and the other red. And it is than a critical disease, in which the disease takes place, with the stronger animals, in the various parts on which this occurs that the disease receives its various names. The deposit is, however, sometimes universal, in the form of a bloody effusion throughout the whole skin. In others, swellings form on the joints, or on the gait, the skin, and, in fact, not uncommon from their attacks. Sometimes the animal swells generally or partially, and the air being suffused under the skin, cracksle to the feel. After any of these appearances have come on, the disease assumes a very malignant type, and is highly contagious. (641.)

Treatment of Inflammatory Fever. Before the critical abcesses form, or at the very outset of the disease, bleed liberally, and purge also: give likewise a fever drink. (6579.) If, however, the disease be not attended to in this early stage, carefully abstain from bleeding, or even purging; but instead, throw upon the water and salt to empty the bowels, and in other respects treat as detailed in the malignant epidemic. (6436.) It may be added, that some drachms of muriatic acid in three pints of oak bark decoction, given twice a day, has proved useful. The swellings themselves may be washed with warm vinegar, both before and after they burst. The cow-house should be fumigated daily.

Cough or influenza in cattle, also known by the name of felon, is only a more mild form of the next disease. Even in this mild form it is sometimes epidemic, or prevalent among numbers; or endemic by being local. Very stormy wet weather, changing frequently, and greatly also in its temperature, produces these cases. We have seen it brought on by change of food from good to bad; and from too close pasturage. It first appears by a defluxion from the nose; the nostrils and eyelids are red; the animal heaves, is sunk up in the flanks, and on the third day he loses the cud. There is a distressing and painful cough, and not infrequently a sore throat also, in which case the beast almost invariably holds down the breath. The treatment is not at all different for cows and horses.

Blessing only the first two days, carefully sheltering, but in an open airy place, and littering well up.

The malignant epidemic influenza is popularly called the murrain or pest; and has at various times made terrible havoc among cattle. Ancient history affords ample proof of its long existence; and by the accounts handed down, it does not seem to have varied its types materially. In 1757 it visited Britain, producing extreme fatality among our kite. From 1710 to 1714 it continued to rage on the Continent with unabated violence. Cattle in the United Provinces suffered great. The years 1738 and 1739, and from 1744 to 1746, witnessed its attack, and produced many written descriptions of it, among which stand pre-eminent that of Sauvages, the celebrated professor of medicine at Montpellier. The British visitation of the malady in the year 1758 elicited an excellent work on the subject by Dr. Layard, a physician of London, which was afterwards translated into several other languages.

Symptoms of the Murrain. Dr. Layard describes it as commencing by a difficulty of swallowing, and breathing. In the early stages, choking the ear, shaking the head, with excessive weakness and staggering gait, which occasioned a continued desire to lie down. A sort of livor of the fetid disease, etc. A drowsiness increased, attended with agitation of the eyes also. The cough was frequent and urgent. Fever exacerbating, particularly at night, when it usually produced quickened pulse. There was a constant scouring of green fetid dung after the first two days, and at every critical. The breath was fetid; even the nostrils, mouth, and eyes exuded an offensive odour. Little tumours or boils were very commonly felt under the skin, and, if about the seventh or ninth day these eruptions become larger, and boils or buboes appeared with a lesseened discharge of faces, they proved the animal suffering. Sometimes, however, it occurred, but if of this constitution, the scouring continued, and the breath became fetid, and the mouth dark in colour, he informs us, mortality followed. Sauvages describes the murrain as showing itself by trembling, cold shivers, nose exserted with an acrid discharge from it; purging after the first two days, but previous to which there was often constiveness. Great tenderness about the spine and withers was also a characteristic, with emphysema, or a blowing up of the skin by air discharged underneath it.

Dissections of those that have died of this disease, according to Sauvages, have shown marks of great inflammation of the head and of a general and intense tendency; gangrene and putrefaction of the fluid secretions, however, always were sufficiently dissolved and broken down by putridity. The paunch, he says, was usually filled with undigestet matter, and the other stomachs highly inflamed; the gall bladder was distended, with a solid thick black bile, which, who likewise dissected these subjects, describes the gall as particularly profuse and intolerably fetid. When he chose to him the whitest part of the boac clav, from the mouth to the arms, was excavated; and Lancisi, contrary to Sauvages, found the visceræ of the chest and belly, in some cases, sphaerated and gangrenous. Gazeta describes the murrain as accompanied with Hebraeans Disposures; and so great was the pestilential tendency, that even the milk, before it dried up, which it usually did before the fourth day, became fetid.
694. The treatment of the murrain. In the very early stages, all eminent authors recommend bleeding; but which should not only be condemned, because the animal's previous health and condition can bear it. The animals must be placed in an open airy place; the litter should be frequently renewed; and the place itself be fumigated with the preventive fumigation. (688.) It has been recommended to burn green boughs with pitch as a substitute; even though this place would be used for cattle in the bottom, these are to be washed with aromatic herbs in water; but vinegar would have been better. In the early stages, saline purgatives, as from ten to twenty ounces of Epsom salts, are to be invariably used. If the scouring have already commenced, they should be only half the quantity, and continued perorally by means of the morbid bile; and if excessive weakness do not come on, the same may be advantageously repeated. Septon are also recommended in the delwp. When abscesses appear, they may be opened, and their contents discharged, washing the wound with brandy or vinegar, and plugging them with the same. The emulsions of tincture of belladonna are very serviceable, and must be kept under lock and key from children. (583.) If the patient is too debilitated, a compost of digitalis and opium should be given. The diarrhoea and micturition should be husked and nether exposed to sun or wind for some time, and the feeding should be nutritious.

694. The prevention of the murrain, or the prevention of its spreading, in many respects is even more important than its medical treatment. It has already appeared that all the other animals may be equally affected; particularly the oxen, swine, and horses, which are more conducive than others to the murrain. It is indubitable that the quick and hard putrefaction, with heat and redness in the mouth and nose; the belly is hard and painful, and the stools, when they appear, are covered with filth. When the mouth and nose discharge a serous fluid, the animal usually dies.

695. Diarrhoea. Bleed at first; but all the stools should be discharged by saline purgatives. (583.) After this give large quantities of nitrated water, and glister also largely.

696. The hore or blowl in cattle is also an inflammatory affection of the paunch, ending in paralysis and rupture of its substance. From the frequency of its occurrence, and because it is probably the most dangerous of all the diseases, a paper on this subject has already appeared in the Transactions of the Royal Veterinary College. Dr. Layard, of Edinburgh, is said to have cured eighteen out of twenty hoved cows, by giving a pint of

697. Treatment There are three modes of relieving the complaint, which may be adverted to according to the degree of distention, and length of time it has existed. These are internal medicines; the introduction of a prodig of some kind, and the paunchy. Of these, the paunchy is the preferable, as the patient, according to the purpose, and the kind of animal to be operated upon. There is a long flexible tube for giving an emetic to horses and cattle (a), and a smaller one for dogs. (b) To relieve hore bullocks, it is useless. It is necessary not only to free the stomach from all the enem, and the very mucous mixture with which they have been long deprived,—as potatoes, turnips, the various grains, particularly red clover; they eat greedily, and forget to lie down to ruminate, by which means the first stomach, or paunch, becomes a distended and is to be expelled by expelling its contents. From this information for a large quantity of air is let loose, which still adds to the distention, till the stomach either bursts, or, by its pressure on the diaphragm, the animal is suffocated. The situation of the beast is known by the uneasiness and general swelling of the abdomen; with the circumstances of the animal being found with such food, or the presumption that it has met with something dead.

698. The anatomy of the brain, called also sough, now and then, but by no means frequently, attacks cattle. The symptoms differ but little from those which attack horses. The treatment must be exactly similar.

699. Inflammation of the lungs occasionally occurs in cattle, in which also the symptoms, progress, and proper treatment are similar to those detailed under that head in horse pathology.

701. The treatment of the sprouts from poison, is similar. When the nature of the poison is discovered, the treatment detailed under poison in horse pathology must be pursued. But there is a species of indigestion to which cattle are liable in the spring, from eating voraciously of the young sprouts of wood, to which some woods are more conducive than others. The symptoms are acute inflammation of the lungs, which they have been long deprived,—as potatoes, turnips, the various grains, particularly red clover; they eat greedily, and forget to lie down to ruminate, by which means the first stomach, or paunch, becomes a distended and is to be expelled by expelling its contents. From this information for a large quantity of air is let loose, which still adds to the distention, till the stomach either bursts, or, by its pressure on the diaphragm, the animal is suffocated. The situation of the beast is known by the uneasiness and general swelling of the abdomen; with the circumstances of the animal being found with such food, or the presumption that it has met with something dead.

702. The bowels hold in cattle is also an inflammatory affection of the paunch, ending in paralysis and rupture of its substance. From the frequency of its occurrence, and because it is probably the most dangerous of all the diseases, a paper on this subject has already appeared in the Transactions of the Royal Veterinary College. Dr. Layard, of Edinburgh, is said to have cured eighteen out of twenty hoved cows, by giving a pint of

703. Treatment There are three modes of relieving the complaint, which may be adverted to according to the degree of distention, and length of time it has existed. These are internal medicines; the introduction of a prodig of some kind, and the paunchy. Of these, the paunchy is the preferable, as the patient, according to the purpose, and the kind of animal to be operated upon. There is a long flexible tube for giving an emetic to horses and cattle (a), and a smaller one for dogs. (b) To relieve hore bullocks, it is useless. From this information for a large quantity of air is let loose, which still adds to the distention, till the stomach either bursts, or, by its pressure on the diaphragm, the animal is suffocated. The situation of the beast is known by the uneasiness and general swelling of the abdomen; with the circumstances of the animal being found with such food, or the presumption that it has met with something dead.

708. The anatomy of the brain, called also sough, now and then, but by no means frequently, attacks cattle. The symptoms differ but little from those which attack horses. The treatment must be exactly similar.

709. Inflammation of the lungs occasionally occurs in cattle, in which also the symptoms, progress, and proper treatment are similar to those detailed under that head in horse pathology.

710. The treatment of the sprouts from poison, is similar. When the nature of the poison is discovered, the treatment detailed under poison in horse pathology must be pursued. But there is a species of indigestion to which cattle are liable in the spring, from eating voraciously of the young sprouts of wood, to which some woods are more conducive than others. The symptoms are acute inflammation of the lungs, which they have been long deprived,—as potatoes, turnips, the various grains, particularly red clover; they eat greedily, and forget to lie down to ruminate, by which means the first stomach, or paunch, becomes a distended and is to be expelled by expelling its contents. From this information for a large quantity of air is let loose, which still adds to the distention, till the stomach either bursts, or, by its pressure on the diaphragm, the animal is suffocated. The situation of the beast is known by the uneasiness and general swelling of the abdomen; with the circumstances of the animal being found with such food, or the presumption that it has met with something dead.

711. Treatment There are three modes of relieving the complaint, which may be adverted to according to the degree of distention, and length of time it has existed. These are internal medicines; the introduction of a prodig of some kind, and the paunchy. Of these, the paunchy is the preferable, as the patient, according to the purpose, and the kind of animal to be operated upon. There is a long flexible tube for giving an emetic to horses and cattle (a), and a smaller one for dogs. (b) To relieve hore bullocks, it is useless. It is necessary not only to free the stomach from all the enem, and the very mucous mixture with which they have been long deprived,—as potatoes, turnips, the various grains, particularly red clover; they eat greedily, and forget to lie down to ruminate, by which means the first stomach, or paunch, becomes a distended and is to be expelled by expelling its contents. From this information for a large quantity of air is let loose, which still adds to the distention, till the stomach either bursts, or, by its pressure on the diaphragm, the animal is suffocated. The situation of the beast is known by the uneasiness and general swelling of the abdomen; with the circumstances of the animal being found with such food, or the presumption that it has met with something dead.
abdomen, which would occasion an equal distention. As soon as the air is perfectly evacuated, and the paunch resumes its office, the trochar may be removed; and, in whatever way it is done, the wound should be carefully closed with sticking plaster or other adhesive matter. It is necessary to observe, that this operation is so safe, that whenever a medical assistant cannot be obtained, no person should hesitate a moment about doing it himself. After relief has been afforded by means of either the probang or the paunching, a stimulant drink may yet be very properly given, such as half a pint of common gin; or one ounce of spirit of hartshorn in a pint of ale, or two ounces of spirit of turpentine in ale, may any of them be used as an assistant stimulant. When also the cud is again chewed, still some relaxation of the digestive organs may remain; at first, therefore, feed sparingly, and give, for a few mornings, a tonic. (6551. No. 1)

6554. Inflammation of the bowels, or red colic, is by no means unknown in cattle pathology; the symptoms of which do not differ from those common to the horse, and the treatment also is in every respect the same. (6165.)

6555. Inflammation of the liver, or hot yellowens, sometimes occurs, in which case, in addition to the symptoms detailed under hepatitis in the horse (679.), there is, from the presence of cystic bile in the ex, a more determined yellowness of the eyelids, mouth, and nostrils; the treatment must be similar. (6479.)

6556. Inflammation of the kidneys, called red water by the cow-leeches, is not uncommon among cattle, and is, perhaps, dependent on the lobulated form of these parts in them. The animal, to the other symptoms of fever, adds stiffness behind, and often straddles, but always shrinks on being pinched across the loins, where frequently increased heat is felt; the urine is sometimes scanty, and now and then increased in quantity, but it is always red, then purple, and afterwards brown or black, when a fatal termination may be prognosticated. The treatment has been fully detailed under nephritis, in the horse pathology (6481.), and it consists in plentiful bleedings, &c., carefully abstaining from the use of diuretics, as advised by ignorant cow-leeches.

6557. The black water is only the aggravated and latter stages of the above.

6558. Inflammation of the bladder also now and then occurs, and in nowise differs from the cystitis of the horse in consequences and treatment. (6482.)

6559. The colics of cattle arise from different causes; they are subject to a spasmodic colic, not unlike that of horses, and which is removed by the same means. (6474.) Continence also brings on a colic in them, called clav bound, farwell bound, &c., which often ends in the red colic, unless early removed; the treatment of this we have fully detailed. (676.) Another colic is accompanied with relaxation of bowels.

6560. Diarrhea, scouring, or scouring colt, is common in cattle, and is brought on by exposure to rain, improper change of food, over-driving, and other violence. It is essentially necessary that the animals be taken under cover, kept warm and dry, and have nutritious food allowed them. The medical treatment has been detailed. (6473.)

6561. Dysentery, or brassy, bloody ray, and slimy far, differs from simple scouring, in a greater degree of fever attending it, and in its being an inflammation of a particular kind, and part of the intestines. It is frequently dependent on a vitiated putrid state of the bile, brought on by over-driving in hot weather, low damp pastures in autumn, &c. The discharge is characterised by its bad smell, and by the numerous stringy patches in it, and also by its heat and smoking when voided; all which are very different from the mere discharge of the alimenta in a state of solution in diarrhoea, and which differences should be carefully marked, to distinguish the one from the other: treat as under diarrhoea in the horse. (6470.)

6562. Yellow's. When acute fever is not present, and yet cattle are very dull, with great yellowness of eyelids, nostrils, &c., it arises from some biliary obstruction, to which oxen and cows are more liable than horses, from their being furnished with a gall bladder; it is a more common complaint in some of the cold provinces on the Continent, where they are housed and stall-fed all the year round, than it is in England. The treatment is the same as detailed for chronic inflammation of the liver in horses, (6481.) adding in every instance to it a change of pasturage, and if convenient, into salt marshes, which will alone often effect a cure.

6563. Loss of the cud. This enters the list of most cow-leeches' diseases, but is less a disease than a symptom of some other affection; indeed it is evident that any attack sufficient to destroy the appetite, will generally occasion the loss of the cud. It is possible, however, that an occasional local affection or paralysis of the paunch may occur, particularly when it is distended with unhealthy substances, as acorns, crab, the tops of some of the woody shrubs, &c. The treatment, in such cases, consists in stimulating
the stomach by tonics, as aloe, pepper, and gin mixed: though these as liquids, may not enter the stomach in common cases, yet in this disease or impaired action of the rumen they will readily enter there. 6964. Staggers, daze, or turning, are sometimes the consequences of over-feeding, particularly when from low keeping cattle are suddenly moved to better pasturage. Treat with bleeding and purging.

6965. Teeth or locked jaw, now and then attacks cattle, in which case it presents the same appearance and requires the same treatment as in horses. (6432.)

6966. Cattle surgery is in no respect different from that in practice among horses, the wounds are treated in the same manner. Goring with the horns will sometimes penetrate the cavity of the belly, and let out the intestines: the treatment of which is the same as in the horse. (6477.) Strains, bruises, &c, are also to be treated like those of horses.

6967. Foul in the foot. This occasionally comes on of itself, but is more often the effect of accident: cleanse it well, and keep it from dirt: — apply the foot paste. (6552.)

6968. Worms, or pockcridges, are tumours on the back of cattle, occasioned by a dipterous insect which punctures their skin, and deposits its eggs in each puncture: these tumours are erroneously attributed to the farm owl or goat-sucker (Caprimulgus europaeus L.). When the eggs are hatched, and the larvae or maggots are arrived at their full size, they make their way out, and leave a large hole in the hide, to prevent which the destruction of the eggs should be attempted by nipping the tumour, or thrusting in a hot wire.

6969. Cattle obstetrics are not very varied; young cows of very full habits have sometimes a superabundant secretion of milk before calving, which produces fever and heat; sometimes, from cold taken; the same will occur after calving also: in either case, give mild dry food, or hay; bathe the udder also with vinegar and water; in some cases, warm fomentations do best. If the fever run high, treat as under fever in horse pathology.

6970. The process of calving is usually performed without difficulty; sometimes, however, cross presentations take place, and sometimes a constriction of parts prevents the natural passage of the calf. To act properly on these occasions, great patience is required, and much militiness: many cows have been lost by brutal pulling; we have seen all the men and boys of the farm mustered to pull at a rope affixed about a calf, partly protruded, which, when it was thus brought away, was forced to be killed, and the mother soon died also from the protrusion of parts this brutal force brought with the calf. A steady moderate pull, during the throes of the animal, will assist much; having first directed the attention to the situation of the calf, that the presentation is such as to obstruct its progress; if it does, the calf must be forced back into the uterus or placed a little right.

6971. Whethering, or retention of the after-birth or burden. — It sometimes happens that this is retained; for which no better remedy has been hitherto discovered than warm clothing and drenching with ale, administered as a forced drench.

6972. The diseases of calves are principally confined to a species of convulsions which now and then attack them, and which sometimes arise from worms, and at others from cold. When the first cause operates, it is then relieved by giving a mild aloeetic purge, or in default of that, a mild dose of oil of turpentine, as half an ounce, night and morning. In the second, wrap up the animal warm, and drench with ale and laudanum a draught. Calves are also very subject to diarrhoea or scouring, which will readily yield to the usual remedies. (6552.)

SECT. II. The Buffalo. — Bis bubalis L. Buffle, Fr.; Buffalo, Span.; Bifflloch, Ger.; and Bufle, Ital.

6973. The buffalo is found wild in India, America, and various parts of the globe, and is in some degree domesticated in many countries. He is gregarious, docile, alert, and of surprising strength; his carcass affords excellent beef; and the horns, which are jet black, and of a solid consistence, take a polish of wonderful beauty: they can be converted into fabrics of use and ornament, such as mugs, tumblers, knife-handles, &c. In this way they sometimes apply them; and when ornaments of silver or mother-of-pearl are employed, the contrast with the polished black of the horn isagreeably striking. The boss on the shoulders is, as well as the tongue, extremely rich and delicious, and superior to the best English beef. It is usual to cure the tongues for sale. The buffalo far surpasses the ox in strength. Judging from the extraordinary size of his bones, and the depth and formation of his chest, some consider him twice as strong as the ox; and, as an animal of labour, he is generally preferred in Italy. In this country the ingenious physiologist, Hunter, has caused buffaloes to be trained to work in a cart. At first they were restive, and would even lie down; but afterwards they became steady, and so tractable that they were driven through the streets of London, in the loaded cart, as quietly and steadily as in Italy or India.

6974. The buffalo is kept in several gentlemen's parks as an object of luxury, and has been trained and worked by Lords Sheffield, Egremont, and some other amateur agriculturists. Many prefer his flesh, and some his milk, to that of the bull family.

6975. The breeding, rearing, and general treatment of the buffalo may be the same as those of the bull family.

CHAP. V.

The Dairy and its Management.

6976. The manufacture of butter and cheese is of necessity carried on where the milk or raw material is at hand. The subject therefore forms a part of farm management, more or less on every farm; and the principal one in dairy farms. In most of those counties where the profit of the cow arises chiefly from the subsequent manufacture of the milk, the whole care and management of the article rests with the housewife, so that the farmer has little else to do but to superintend the depasturing of his cattle; the
milk, churning, and in short the whole internal regulation of the dairy, together with the care of marketing the butter, where the same is made up wholly for home consumption, falling alone upon the wife. In this department of rural economy, so large a portion of skill, of frugality, cleanliness, industry, and good management, is required in the wife, that without them the farmer may be materially injured. This observation will indeed hold good in many other parts of business which pass through the hands of the mistress in a farm-house; but there is none wherein he may be so greatly assisted, or so materially injured, by the good conduct or want of care in his wife, as in the dairy. The dairy husbandry is more extensively and successfully pursued in England than in Scotland or in Ireland. "As to dairy husbandry on any thing like an improved plan," says Aiton, "it is still confined to a mere corner of Scotland." This corner is the district of Cunningham, in Ayrshire, of which he observes: "The excellence of the improved breed of cows in Ayrshire, as well as the superior quality of Strathaven veal, the Glasgow butter and milk, and Dunlop cheese, to all others in Scotland, are things that cannot be disputed." (Aiton's Dairy Husbandry, Pref. p. 18.) We shall in giving the dairy husbandry of England glance, at the same time, at the peculiarities of the Ayrshire dairy husbandry, as given by the author last quoted.

097. The operations of the dairy in all its branches are still conducted perhaps more empirically than those of any other department of husbandry, though it would appear that science, chemistry in particular, might be applied to discover the principles, and regulate the practice, of the art, with facility and precision. We are assured by the most experienced and practical author observers from the animal, that the quality of their cheeses differs materially in the same season, and without being able to assign a reason. Every one knows how different the cheese of Gloucester is from that of Cheshire, though both are made from five to seven pence worth of cows, or rather from the same breed, or of the same breed, as is fed on pastures that do not exhibit any remarkable difference in soil, climate, or herbage. Even in the same district, some of what must appear the most important points are far from being settled in practice. Marshal, in his Rural Economy of Gloucestershire, has regard to the number of observations as follows: of the ancient art of perfect cheese-making; the rennet was supplied in cheese-making; on the time required for coagulation, and the heat of the whey after, which are curious, only because they prove that no uniform rule is observed in any of these particulars. The same discrepancy is observable in all the subsequent operations of the art, and in the manner in which the solid product is removed from the press, a style of churning which would lead the observer to think the process of salting the cheeses the most simple of all; and yet it is sometimes, as in the west of Scotland, mixed with the curd; in other instances poured into the milk, in a liquid state, before being coagulated; and still more commonly, never applied at all till the cheese are separated by the forced pressure of the cheese-press; a practice of the greatest extent. In treating of the dairy, we shall first offer a few remarks on the nature of milk, and the properties of that of different animals; and next consider the dairy house and its furniture, milk-, churning-, cheese-making, and the different kinds of cheese, butters, creams, and other products of the dairy.

0875. The milk used by the human species is obtained from various animals, but chiefly the cow, ass, ewe, goat, mare, and camel; that in most general use in British dairying is the milk of the cow, which in modern times has received great improvement in quantity as well as quality, by ameliorations in the form of milk cows, in their mode of nourishment, and in the management of the dairy. Whatever be the kind of animal from which milk is taken, its external character is that of a white opaque fluid, having a sweet smell, and a specific gravity somewhat greater than water. The milk is so viscid, that when it is strained, and allowed to remain at rest, it separates into two parts; a thick white fluid called cream, which collects on the surface in a thin stratum; and a more dense watery body, which remains below. The quantity and quality of cream and the tinction which requires to separate it from that of the milk and the temperature of the atmosphere. Milk which has stood some time after the separation of the cream, becomes aerescence, and then coagulates. When the coagulum is pressed gently, a serous fluid is forced out, and the remainder is the caseous part of milk, or pure cheese.

0890. The solidified cream, with which the products of milk are obtained artificially by churning; an operation analogous in its effects to shaking or beating, by which the cream separates from the caseous part and serum, in a more solid form than when left to separate spontaneously. It is afterwards rendered still more solid by beating with a wooden paddle of muriate and phosphate of lime. The caseous part of milk, or the coagulum, which is the solid part of the milk after the separation of the salts is converted by cooling into a gelatinous substance. If whey be kept it becomes sour, by the formation of an acid, which is called the lactic acid; and it is to this that the spontaneous coagulation of milk, after it remains at rest, is owing. Milk may, after it is sour, be fermented, and it will yield a vinous intoxicating liquor, which is called in some parts of Scotland, the morn, and in others, the Tartars with the milk of the mare. Milk is likewise susceptible of the acetic fermentation.

0892. The constituent parts of milk are found to be oil, curd, gelatine, sugar of milk, muriate of soda, muriate of potash, phosphate of lime, and sulphur milk. The fat is constantly formed in the milk, but the variations vary in different species. The various milks in use as food are thus distinguished:—

0893. Cow's milk produces a copious, thick, and yellow, cream, from which a compact consistent butter is formed; the curd is bulky, and retains much serum, which has a greenish hue, a sweet taste, contains sugar of milk and neutral salts, and, by the Tartars, the milk of the cow.

0894. Ass's milk throws up a cream resembling that of woman's milk; the butter made from it is white, soft, and disposed to be rancid; the curd is similar to that of the woman, but not unctuous; the whey is containing less salts, and a greater proportion of sugar, than the cow's.

0895. Eor's milk throws up as much cream as that of the cow, and of nearly the same colour; the butter made from it is yellow and soft; the curd is fat and viscid; the whey is colourless, and contains the smallest quantity of sugar of any milk; but a small portion of muriate and phosphate of lime.

0896. Sheep's milk produces abundance of cream, which is thicker and whiter than that from the cow:
the butter is white and soft, and equally copious, and so is the curd, which is of a firmer consistence than that of the cow, and retains less whey. 6887. Mare's milk produces a very fluid cream, similar in colour and consistence to good cow's milk before the cream appears on the surface; the butter made from it has but little consistence, and is readily decomposed. The curd is similar to that obtained from woman's milk, and the whey has little colour, and contains a large proportion of saccharine matter, and of saline substances.

6888. Camel's milk throws up little cream, which is whitish and thin, affording insipid whitish butter; the curd is small in quantity, and contains but little whey, which is colourless and somewhat saccharine. 6889. Soya's milk. In China, especially about the city of Canton, no other milk can be had but that of the sow. It is rather sweeter than cow's milk, but very similar in all other respects. 6890. In the use of these milks, that of the camel is chiefly confined to Africa and China, and that of the mare to Tartary and Siberia. In India the milk of the buffalo is preferred by the natives to that of the domestic cow. The milk of the goat is more generally used in Italy and Spain than in any other countries in Europe; they are driven into Leghorn, Florence, Madrid, and other towns, in flocks early in the morning, and milked in the streets. The goat will allow herself to be sucked by the young of various other animals, and a foal which has lost its mother has been suckled by a goat, placed on a barrel to facilitate the operation. As the butter of goat's milk contains a larger proportion of gelatine, and less oil than that of the cow, it is recommended by physicians as nearly equally light as ass's milk; it is the most prolific of all in curd, and forms excellent cheese; but it is an error to suppose that the Parmesan (a skim-milk cheese) is made from it. Ewe's milk is gradually wearing out of use, though it makes excellent cheese, and some milking ewes as well as goats might be kept for that purpose, by those who have extensive upland grass-lands. The milk of the ass comes the nearest to that of the woman, and being the lightest of any is much recommended in pulmonary and hepatic affections. Soda water and warm cow's milk is taken as a substitute, and found almost equally light. The milk in universal use, as an article of food in Britain, is that of the cow.

Lactometers for ascertaining the value of milk, relatively to butter and cheese, will be described among the utensils of the dairy in the succeeding section.

**SECT. 11. The Dairy House, its Furniture and Utensils.**

6992. The dairy house, for general purposes, consists of at least three separate apartments, the milk room, the dairying or working room, and the cheese or store-room. The two former are generally separated by a passage or lobby; and the latter is very frequently a loft over the whole, entered by a stair from the lobby.

6993. The proper site of a good milk-house are, that it be cool in summer, and moderately warm in winter, so as to preserve a temperature nearly the same throughout the whole year, or about 45 degrees; and that it be dry, so as to admit of being kept clean and sweet at all times. For these reasons a northern exposure is the best, and this as much under the shade of trees or buildings as possible; if it can be so arranged that the sun can have no influence either on the roof or walls, so much the better.

6994. A well constructed butter dairy should consist of three apartments; a milk-house, a churning house, with proper boiler, as well as other conveniences for scalding and washing the implements, and a room for keeping them in, and for drying and airing them, when the weather will not permit of its being done without doors.

6995. The cheese dairy should likewise consist of three apartments; a milk-house, a scalding and pressing-house, and a salting-house. It is essential to the cheese dairy to have a command of heat during the cold season. When milk is exposed to a degree of cold below 35° at any time, from the moment it is drawn from the cow, till the cheese is not only pressed, but, to a great extent, dried, the cheese will not be good. If it is not enough that the milk be again heated; it must never be allowed to become too cold at any time, not even in the press; or it is, the quality of the cheese will be much injured." (Aiton's Dairy Husbandry, p. 82.) To these should be added a cheese-room or loft, which may have great propriety be made above the dairy. This is, however, generally separate from the dairy. But a milk dairy requires only a good milk-house, and a room for scalding, cleaning, and airing the utensils. The size of the milk-house, according to Aiton, ought to be sufficient to contain one day's milk of all the cows belonging to it.

6996. A dairy for the private use of a farmer or family need not be large, and may very economically be formed in a thick walled dry cellar, so situated as to have windows on two sides, the north and east in preference, for warmth; and in such a situation that these windows may be better exclude cold in winter, and heat in summer, they should be fitted with double sashes, and on the outside of the outer sash should be a fixed frame of close wire netting, or hair cloth, to exclude flies and other insects.

6997. Of dairies for dairy farmers there are different sizes and shapes.

6998. A dairy-house connected with a cow-house, and milk for preparing food for the cows, churning, and washing the family linen, is thus arranged. (Fig. 871.) The dairy (a, b, c, d) is at the north end, has hollow walls, double doors, double sashed windows, and an ice-house under. The milk room (a) is surrounded by milk-coopers, there is a better slab and jet in the centre. The jet is supplied from a cistern over the steaming house (f, g), to which the water is raised from a well by a forcing-pump worked by the
gin wheel. Besides supplying the jet, it furnishes, by cocks and pipes, water for the usual dairy purposes, the steaming or boiling of food for the cows, their drink, and washing out the cow-house, the washing machine &c. The churning room (b), is separated from the milk-room by double doors, as is the latter from the cheese-room (c) and store closet (d). The gin wheel (e) is worked by one or two horses, or oxen or asses, according to the work to be done. The steaming and washing room (f, g) is a large roomy apartment properly fitted up, and furnished with two boilers, a machine for steaming cattle food, another for washing linen by steam; one impelled by the gin wheel operating on an axle with beaters or lifters (fig. 872), and a cylinder of open spars, which turns round in a box of water for washing potatoes or other roots. The cow-house (h, k) is calculated for forty cows to be fed from a broad passage in the centre. At the south end is a large apartment (i) open to the roof for hay, straw, green herbage for feeding, turnips, and other food; and under it is an urinal vaulted, and from which the liquid is drawn by a Buchanan pump (4894) outside of the building, and some yards distant.

6000. The dairy house recommended by Dr. Anderson is surrounded by double walls, the inner of brick or stone, nine inches or a foot in thickness; and the outer about two feet distance, built of stone or turf; or a bank of earth faced with turf may be placed against the inner walls.

7000. The size of the dairy house should vary according to that of the number of cows. Marshal found in Gloucestershire one for forty cows to be twenty feet by sixteen, and one for one hundred, thirty by forty. The North Wilts dairies have in general, he says, outer doors, frequently opening under a pent-house or open lean-to shed; which is a good convenience, affording shade and shelter, and giving a degree of coolness to the dairy room. In one instance he observed two doors; a common close-boarded door on the inside, and an open-paned gate-like door on the outside; giving a free admission of air in close warm weather, and, at the same time, being a guard against dogs and poultry. A convenience which he thinks, would be an improvement to any dairy room in the summer season. The inside wall may be seven or eight feet high in the sides, on which may be placed the couples to support the roof, and the walls at the gables carried up to the height of the couples. Upon these should be laid a roof of reeds, or thatch, that should not be less than three feet in thickness, which should be so placed downward towards the dairy, the whole of the walls on each side to the ground: but here, if thatch or reed be not in such plenty as could be wished, there is no occasion for laying it quite so thick. In the roof, exactly above the middle of the building, should be placed a wooden pipe of a sufficient length to rise a foot above the roof, to serve occasionally as a ventilator. The top of this funnel should be covered, to prevent rain from getting through it, and a valve fitted to it, that by means of a string could be opened or shut at pleasure. A window also should be made upon one side for giving light, to be closed by means of two glazed frames, one on the outside, and the other on the inside. The use of this double sash or sashes is not the great thickness of the walls, and of the thatch upon the roof, are to render the temperature of this apartment as equal as possible at all seasons of the year, by effectually cutting it off from having any direct communication with the external air.

7001. The dairy-house made use of by Walkfield of Liverpool contains three apartments; a milk-house, churning-room, and the room for the utensils. In the milk-house were the coolers; a slab for laying butter on after it is made up; cocks for drawing off the milk from the coolers; a large cock to throw water on the floor, which slops a little from that part; cocks at the back part of the coolers, for letting in water; a door, latticed, and another door most commonly used, but panelled. In the churning-room is a fire-place, a boiler, a large copper, also used when brewing. The room for drying or airing the utensils is also used occasionally as a laundry. Over the whole are apartments for the servants.

7002. A very neat dairy for a private family may be made under the shade of two or three tall trees, in the following manner:—Build the walls of bricks, and hollow in Silverlock's manner, by which every course of brick-work is laid on edge, and forms oblong cavities (fig. 873). a, the bricks of the one course being laid alternately lengthways (b), and crossways (c), and those of the next breaking joint with these, by the cross ones being placed on the middle of the long ones (d). The elevation of such a wall (e, f, g) should of course be founded on solid work, of breadth and thickness according to the height of the wall, and nature of the foundations. The plan of a dairy with such walls should contain the three usual apartments for milk, churning, and utensils (b), and should have double doors and windows: the latter guarded by fly-wire. The elevation (i) may be of any style of simple architecture.

7003. As a complete dairy on a large scale, we submit the following. The plan (fig. 874) is of an oblong form, and consists of the three usual principal apartments, enclosed by walls of four inches in thickness, and surrounded by a passage two feet wide to the north, and three feet to the south, which is again surrounded by a nine-inch wall. The passages communicate with the roof by covered openings, in the ridge of which and by which the windows ventilation is completely effected. In detail, the plan exhibits two principal entrance porches (a), back entrance (b), copper for heating water (c), churning-room (d), milk-room (e), utensils
and cheese-press (f), boiler for heating milk (g), store closet or butter-room (h), cheese-room (j), passage surrounding the whole (k), water-closet (l), and windows to cheese-room (m).

7004. A section (fig. 575) taken across the milk-room (fig. 874 a u) exhibits the ventilating funnel in the roof a, projecting caves (b, c) cheese-room (f) passage on the north side (c), raised part of the roof for ventilation (f, g), fountain in the centre of the dairy (h), and south passage (d).

7005. The elevation (fig. 876) presents a simple shed roof, varied, however, by projections and recesses; it presents no windows on either to the south, and therefore that side, if other circumstances permit, may be covered with vines or other fruit-trees, or with ornamental creepers.

7006. The fixtures of the dairy are, in the scalding-room, a copper boiler fixed over a

fire-place, for boiling water to wash and scald the utensils; next, some benches and shelves in this room and the cheese-room; and a bench or table not more than two feet wide surrounding the milk-room. It is very desirable, also, that there should be a jet, or fountain, or pump, or spring, in the centre of the milk-room, in order to cool down the air in summer, and to supply clear water at a moderate temperature at all times.

7007. The utensils of the dairy are, masts for milking into; sieves of hair-cloth, or silver wire-cloth for passing the milk through, to free it from hairs and other impurities; milk dishes, or coolers, for holding the milk till it throws up its cream; a cream-knife of ivory for separating, and skimming dishes of willow or ivory for removing the cream; bowls and barrels for holding it, or other preparations of milk-churns, butter-makers, butter-prints; one or more tubs for hot or cold water, in which to immerse vessels that require extraordinary purification; and a portable rack for drying dishes in the open air. All these utensils are requisite where butter only is to be produced.

7008. The utensils requisite if cheese is to be made, are the cheese-tub, in which the curd is broken, and prepared for being made into cheese; the cheese-knife, generally a thin spatula of wood, but sometimes of iron, used for the purpose of cutting or breaking down the curd while in the cheese-tub. The cheese-cloth is a piece of thin gauze, like linen cloth, in which the cheese is placed in the press; the cheese-board is circular, and on it the cheeses are placed on the shelves of the cheese-room; their diameter must be somewhat less than that of the interior or hoop part of the vat. The vat is a strong kind of wooden hoop with a bottom, which, as well as the sides, is perforated with holes to allow the whey to escape while the cheese is pressing; the size of vats must depend on that of the cheese and the number required, as of most of the other implements on the extent of the dairy. The cheese-tub is a vessel generally obtained by a screw, though sometimes by a dead weight, and is used for forcing the whey from the curd while in the vat. The cheese-tongs is a wooden frame, occasionally placed on the cheese-tub, when the vat is set on it in order to drain the whey from the curd. To these implements some add a lacometer, one kind of which (fig. 675), is a glass tube a foot long with a funnel at top. The upper two inches of the tube are marked in small divisions, and when the instrument is filled to the height of one foot with milk, the density of cream it yields is noted by the graduations on the upper part. Another lacometer for ascertaining the richness of milk from its specific gravity, by its degree of warmth taken by a thermometer, on comparing its specific gravity with its warmth, was invented by Diacs, of Liverpool, but never came into use. Another invention for the same purpose was made by Mrs. Lovi, of Edinburgh, in 1816. It consists of aeroometric beads, by which the specific gravity of the milk is tried first when new-milked, and next when the cream is removed. When milk is tried as soon as it cools, say to 68°, and again, after it has been thoroughly skinned, it will be found that the skimmed milk is of considerably greater gravity; and as this increase depends upon the separation of the lighter cream, the amount of the increase, or the difference between the specific gravity of the fresh and skimmed milk will bear proportion to, and may be employed as a measure of, the relative quantities of the oily matter or butter contained in different milks. The specific gravity of skimmed milk depends both on the quantity of the saccharo-saline matters, and of the curd. To estimate the relative quantities of curd, and by that determine the value of milk for the purpose of yielding cheese, it is only required to divide the skim-milk, and ascertain the specific gravity of the whey. The
whey will, of course, be found of lower specific gravity than the skimmed milk, and the number of degrees of difference affords a measure of the relative quantities of the curd. According to this hypothesis, the aereometric bowls may be employed to ascertain the qualities of milk, relatively both to the manufacture of butter and cheese. (Trans. of the High. Soc. sect. v. part l.)

7006. In milk coolers and churn there is considerable variation of form. Milk coolers are generally made of earthenware or wood; but of late years they have been formed of lead, marble, slate, and cast-iron. Their general form is round, and diameter from one to two feet; but in extensive dairies they are often made several feet or yards in length, and from two to three feet wide, with holes at one or more corners to admit the escape of the milk after the cream is removed. The safest dish is wood, though it requires most labour to keep it sweet; next is earthenware or China, though on the leaden glaze of the former the acid of the milk is apt to operate. Leaden dishes or troughs, though very general in Cheshire, are the most dangerous; and the objection to slate coolers is the joinings of the plates, which are always unsightly, imperfect, and liable to be operated on by the lactic acid. The annealed and tinned cast-iron dishes of Baird's invention (in 1836), and which are now becoming universal in Scotland (Aiton's Dairy II., p. 81.), are perhaps the best for such as do not choose to go to the expense of China dishes. They are durable from the nature of the material, not liable to be broken by falls by being annealed, easily kept clean from being turned smooth, and also very economical, and said to throw up more cream from a given quantity of milk than any other.

7007. Besides the common plunge and barrel churns, there are various improved sorts. One of the best for using on a small scale is the patent box churn (fig. 879.); and on a large scale, the plunge churn, worked by levers put in motion either by a man or horse. The Derbyshire churn (fig. 881.), which works on the principle of the barrel churn, is an excellent implement on a large scale. The bottom is a segment of a circle, and the advantage of the plan is, that when the butter is made, the lid (a) being removed, the beaters (b) may be taken out at pleasure by withdrawing the spindle (c) to admit the removal of the butter, or the cleaning and scalding of the churn.

7008. The Lancashire plunge churn (fig. 881.) is a simple and effective implement, worked by the operator standing on the levers (a, b), throwing his whole weight alternately on each, so as by means of the line (c, d) connected with the churn staff to raise it and turn it round, and lower it and turn it round alternately.

7012. The most exquisite contrivances in the dairy is an essential requisite, as to the walls, floor, shelves, benches, and in the different utensils.

7013. The milk coolers and all the dishes in which milk is put, as well as the churn, must be scaled, scrubbed, rinsed, and dried every time they are used. Scalding is less frequently requisite in the cheese utensils, but they also must be almost daily washed in hot water, dried, and aired. When any vessel becomes tainted with the acidity of milk, it operates like leaven on what is put into it; if this taint cannot be removed by ordinary scalding, it may by boiling or immersing in water impregnated with alkali; but afterwards it must be well boiled, or a day or two immersed in pure water.

Sect. III. Milking and the general Management of Milk.

7014. The times of milking vary greatly in different districts. In most places cows are milked twice in twenty-four hours throughout the year; but in the best managed dairies where they are abundantly fed, they are milked at morning, noon, and the approach of night: the additional quantity thus obtained is very considerable, but according to the experiments of Parmentier it must be inferior in quality; for he found twelve hours requisite for the due preparation of the milk in the cow. Where quantity of milk or cheese is an object, three times milking must be decidedly preferable; but it is certain that in the best butter districts of England the cows are only drawn twice a day, between five and six o'clock morning and evening. Whatever may be the times of milking, it is essential that the milk be drawn off clear; for if the milk which the cow can be made to yield at the time be not completely taken away, the quantity left will be reabsorbed into the system, and no more will be generated than is necessary to supply the quantity actually drawn off.

7015. The operation of milking is performed by men in many districts, but taking Britain generally it is more commonly the work of women. The milker, whether a man or woman, ought to be mild in manner and good tempered. If the operation be performed harshly, it becomes painful to the cow, who in this
Butter.

1014

ease often brings into action her faculty of retaining her milk at pleasure; but if gently performed, it seems rather to give pleasure, as is exemplified on a large scale in Tiviotdale, and Switzerland, where the cows come to be milked at the call of the milkers. Many instances have occurred, Dr. Anderson observes, in which down brushing the milk to the dairy-maid, which let it flow in abundance whenever another approached them; exhibiting unequivocal marks of satisfaction in the one case, and of sullen obstinacy in the other. For the same reason, when cows are ticklish, they should be treated with the most soothing gentleness, and never with harshness or severity; and, when the udder is hard and painful, it should be immersed in warm water, and the udder milked gently, by which means it is explained the cow will be brought into good temper, and will yield her milk without restraint. Lastly, as it sometimes happens that the teats of cows become scratched or wounded, so as to produce foul or corrupted milk, all account to be made with the sweet milk, but should be given to the pigs, without being carried into the milk-house; lest, by continuing there, it should taint the atmosphere, and consequently prove injurious to the rest of the milk.

7015. To promote cleanliness in regard to making, cows are in some places curried, combed, brushed, and occasionally milked in the cow-house; and washing the udder, is indispensable in every establishment where clean milk is an object. According to Mowbray, quill-takers, slats, and dandies are unfit to be dairy-women, and no milk should ever be suffered to enter the dairy in a dirty apron covered with hair from the cow-house.

7017. The following aphorisms respecting the management of milk in the dairy are from the "Recreations" of Dr. Anderson, one of the most scientific writers on this subject.

1. Of the milk drawn from any cow at one time, that part which comes off at the first is always thinner, and of a much worse quality for making butter, than that afterwards obtained; and this richness continues to increase progressively to the very last drop that can be obtained from the udder.

2. If milk be put into a dish, and allowed to stand till it throws up cream, the portion of cream rising first to the surface is richer in quality, and greater in quantity, than that which rises in the second space of time; and the cream, which rises in the second interval of time, is greater in quantity, and richer in quality, than that which rises in the third interval; and so on, till the cream begins to separate from the udder; and to discontinue the process of time, and to decline in quality, so long as any rises to the surface.

3. Thick milk always throws up a richer proportion of the cream which it actually contains than milk that is thinner; but the cream is of a richer quality: and if water be added to that thick milk, it will afford a considerably greater quantity of cream, and consequently more butter than it would have done if allowed to remain pure; but its quality is, at the same time, greatly debased.

4. Milk, when poured into a proper vessel, and carried a considerable distance, as so as to be much agitated, and in part cooled before it is put into the milk-pans to set for cream, never throws up so much, or so rich cream, as if the same milk had been put into the milk-pans directly after it was milked.

7018. From these fundamental facts, the reflecting dairyist will derive many important practical rules. Some of these we shall enumerate, and leave the rest to be discovered. Cows should be milked as near the dairy as possible, in order to prevent the necessity of carrying and cooling the milk before it is put into the cream-pans; and the udders kept separate till the milk be, as far as possible, well known as to admit of their being classed, those that are most nearly allied may be mixed together. When it is intended to make butter of a very fine quality, reject entirely the milk of all those cows which, in the form of a bad quality, and keep the milk that is first drawn from the cow at each milking entirely separate from that which is last obtained, as the quality of the butter must otherwise be greatly debased without materially augmenting its quantity. For the same purpose, take only the cream that is first separated from the first drawn milk. Butter of the very best quality can only be economically made in those dairies where cheese is also made; because in them the best part of each cow's milk can be set apart for throwing up cream, the best part of this cream can be taken in order to be made into butter, and the remainder, or all the rest of the milk and cream of the dairy, can be turned into cheese. The spontaneous thickening of butter, are never reflected but in consequence of the production of acid in the milk. Hence it is that where the whole milk is set apart for the separation of cream, and the whole of the cream is separated, the milk must necessarily have turned sour before it is made into cheese; and no very excellent cheese can be made from milk which has once attained that state.

7019. The milk from which butter is to be made may either be put at once into the churn, and left there till it send up the cream; or it may be made to cream in milk dishes, and the cream alone churned.

7020. The last is generally considered the best mode, and in carrying it into effect, the milk being drawn from the cow, is to be strained into the creaming dishes, which should never be more than three inches deep, and of about a gallon and a half or two gallons in capacity. In general the best cream will be fit for removal in seven or eight hours; though for ordinary good butter it may stand twelve hours; but the udders of cows so arranged as admit of the milk to cheese, or some other use while it is sweet, it may be separated after standing only two or three hours. To perform the operation, first pass the cream knife round the edges of the vessel, to separate the adhering stratum of cream, and then draw it to one side, lift it off with the skimming dish, and put it into the churn tared.

7021. Cream may be kept from three to seven days before it is churned. Where quantity more than quality is desired, the whole of the milk is churned, without separating any cream; the milk is kept in the churn; the large bowls of the churn are removed three days, to allow the butter to be separated from the cream, where the cream and milk are both to agitate, is necessarily tedious and laborious; but a great weight of butter is undoubtedly obtained, the quality and flavour of which will depend a good deal on the peculiar properties of the milk. The milk of Galloways, Ayshires, and Alderneys, so treated, makes excellent butter.

7022. In the process of curdling, great nicety is required; a regular stroke in plunge or pump churns, and a regular motion in those of the barrel or turning kind, must, if possible, never be deviated from. A few hasty irruptions to spoil what was before gained, are to be avoided. The operation of curdling is called "laying" the butter. Trowley (Essays on the Dairy) recommends the selection of a churner of a cool phlegmatic temper, of a sedate disposition and character; and advises never to allow any individuals, especially the young, to assume caution and circumstance. To those who have been accustomed to see cream churned without being properly prepared, curdling may, perhaps, appear to be severe labour for one person in a large dairy; but nothing is more easy than the process of making butter, where the cream has been duly prepared.

7023. The best time for making butter, during summer, is early in the morning, before the sun acquires much power; and if a pump churn be used, it may be plunged a foot deep into a tub of cold water, where
it should remain during the whole time of churning; which will very much harden the butter. During winter, from the equality of temperature, which (if it be properly managed) will generally prevail in a dairy house, where the butter is rarely, if ever, necessary to churn; however, if you require this, care should be taken not to churn so near the fire as to heat the wood; as it would impart a strong rancid taste to the butter. As soon as the butter is made, it must be separated from the milk, and be put into a clean dish; the made of which, if of wood, should be previously well rubbed with common salt. In this vessel the butter should be kept, if only partly worked, to prevent the common lard, or skimmed, dish, having a short handle, so as to press out all the milk that may be lodged in the cavities of the mass. A considerable degree of dexterity, as well as of strength, is requisite in this manipulation: if the milk be not entirely removed from the butter, and if it be much worked, the butter will become tough and gluey, which greatly degrades its quality. In some places it is the practice to heat up the butter with two flat pieces of board, which may, perhaps, answer very well. In this operation, some persons prefer the practice of applying to the surface of the butter a layer of salt, both to prevent the hardening of the butter, and to the great extent of the milk, without it, but it is also pernicious, and degrades the quality of the butter in an astonishing degree. Nothing so detrimental in a dairy as water improperly used; which, if mixed in any way, either with milk or butter, is necessary, in order to debase the quality of the butter.

7024 The best temperature for churning butter has been very satisfactorily determined by a number of experiments, sanctioned by the Highland Society of Scotland, and published in their Transactions. From these experiments it is concluded, that the proper temperature of churning butter for the most proper result, and that at no time in the operation ought it to exceed 63°; while, on the contrary, if at any time the cream should be under 55° in temperature, the labour will be much increased, without any proportionate advantage being obtained; and a temperature of a higher rate than 65° will be injurious, as well to the quality as the quantity of the butter. (.Highl. Soc. Trans. vol. vii. p. 138.)

7025 The making up of butter is the next process.

7026 Before being sent in table or market, sweet or fresh butter is made up into various forms; sometimes into rolls or cylinders, six or eight inches long, and from half an inch to two inches in diameter; or other times into small round figures, or cylindrical shapes; and is afterwards placed in vessels, both in the dry and the wet state; and it may be put into small wooden vessels, which may be allowed to swim in a tub or cistern of cold water; or they may be set in an ice-house for an hour or two; or the water in which the small vessels float may be iced. At all events, whatever mode is adopted, no water ought to be allowed to touch the butter. When formed into the desired shapes, it may be placed in dishes, and set in the margin of the central cistern of salt water till wanted.

7027 In salting or curing butter the use of wooden vessels is preferable; and these vessels should be made from timber which has been previously boiled for four hours, to free it from the pyrolignous acid; or they should be formed from the lime tree, which is sufficiently asserted (.Highl. Soc. Trans. vol. vii. p. 355.) to be without this acid. Whatever description of casks are used, they should previously be rendered as clean and sweet as possible, well rubbed with salt, and the cavity between the bottom and sides filled in with melted butter.

7028 An excellent composition for preserving butter may be made, by reducing into a fine powder, and carefully mixing together, sugar, of each one part, and two parts of the best common salt. Moir, in his Art of Making Butter, says:—Cut the wood into square deals of the lengths wanted; have a boiler of a square form, the length of the wood, full of water; put in the wood with a weight or pressure, to keep it immersed in the water, and have a wooden cover on the boiler, as it may be necessary to prevent the close evaporation of the waters, and when this boiler of the pyrolignous acid will be extracted. The wood is then dried for use. It becomes closer and more condensed, from the fibres being compacted. By this method, while the wood continues hot, it can be easily brought to any shape, and used for various purposes; and this is the only mode by which barrels for salted butter should be filled: (.Highl. Soc. Trans. vol. vii. p. 285.)

7029 When butter is to be exposed to the heat of a warm climate, it should be purified by melting before it is salted and packed up. For this purpose, let it be put into a proper vessel, and this be immersed into an equal weight of cold water. Let the water be heated till it becomes boiling in this state for some time, when the impure parts will subside, leaving at the top a perfectly pure trans- parent oil. This, when it will, becomes opaque, and assume a colour nearly resembling that of the original butter, being only somewhat paler, and of a firmer consistence. When this refined butter is cooled, but while it is still a little bit soft, it is to be part powdered, and, being salted and packed up in the same manner as other butter, it will continue sweet much longer in hot climates, as it retains the salt better than in its original state. It may also be preserved sweet, without salt, by adding to it a certain portion of fine honey, perhaps one ounce to a pound of butter, and mixing them together thoroughly, so that they may be perfectly incorporated. A mixture of this sort has a sweet pleasant taste, and will keep for years without becoming rancid: there is no doubt, therefore, but that butter thus might be preserved in long voyages without spoiling.
As winter-made butter is mostly pale or white, and, at the same time, of a poorer quality than that made during the summer months, the idea of excellence has been associated with the yellow colour; hence, various articles have been employed in order to impart this colour. Those most generally used, and certainly the most wholesome, are the juice of the carrot, and of the flowers of the marigold, carefully expressed, and strained through a linen cloth. A small quantity of this juice (and the requisite proportion is never ascertained by experience) is diluted with a little cream, and this mixture is added to the rest of the cream when put into the churn. So small a quantity of the colouring matter unites with the butter, that it never imparts to it any particular taste.

2572. The butter most esteemed in London is that of Epping and Cambridgeshire, which produces this colour. The same is also seen during summer in the shrubby pastures of Epping forest, and the leaves of the carrot and marigold, on being steeped in milk and boiled, are employed for the purpose of imparting the colour. In this respect, these two counties are equal, and often, when these liquids are mixed, the best butter is produced. The butter of Cambridgeshire is produced from the milk of cows that feed one part of the time on the Epping moors, and another on rich meadow lands, or on grass, if it is made up in long rolls like the Epping butter, and generally salted, not curdled, before being condensed. From the latter it has been taken out of the old cheeses, which, when salted out of it, the London cheesemongers often sell at a high price.

2573. The Suffolk and Yorkshire butter is often sold for that of Cambridgeshire, to which it is very much similar. The butter of the Somersetsire is thought to equal that of Epping; it is brought to market in dishes, containing half a pound each, out of which it is taken, washed, and put into different forms by the buttermen of Bath and Bristol. The butter of Gloucestershire and of Oxfordshire is inferior, as it is not produced from these same two counties, but is made from the milk of cows that feed on grass or prints, packed up in square baskets, and sent to the London market by waggon.

2574. The butter of the mountains of Wales and Scotland, and the moors, covered with tundra and heath, is of excellent quality, when it is properly managed; and though not equal in quantity, it often is considerably superior to that produced from the richest meadows. Bad butter is more frequently the result of mismanagement, want of cleanliness, and inattention, than of any other cause. Some other countries produce good butter; but, in the best butter in the empire, were not for the intolerably filthy state of their cows, and the want of cleanliness in their dairies.

2575. In picking fresh butter, or butter salted only for immediate use, the leaves of cabbages, white beet, or of the garden orache (C. hortêae) are to be preferred. The bottom of the basket should be bedded with a thick cloth, folded two or three times, then a thin gauze, dipped in cold water, spread over it, on which the prints or rolls of butter are to be placed, each with one or more leaves beneath, and smaller ones over it. The lowest layer being adjusted, fold half of the gauze cloth over it, put in another layer in the same way, and then cover with the remainder of the gauze. The butter should be put in the basket, without being touched.

2576. Whey butter, as its name implies, is made from the whey which is taken from the curd, after the milk is coagulated for the manufacture of cheese. It is chiefly made in those counties where the same milk is used for the manufacture of Derby more butter is said to be made from whey from the cream of milk, or from milk churned altogether.

2577. When divided into two sorts, green and white, the former escaping readily from the curd, while the latter is removed from it by means of pressure. "There are different methods of extracting the whey. In some dairies the whole whey, when taken from the cheese-cist, is put into pans or other vessels, where it remains for about twenty-four hours; when it is creamed, and the whey is applied to the use of calves and pigs, the whey being taken from the curd, and the cream, when skimmed off the whey, is put into a brass pan and boiled, and afterwards set in pans or jars, where it remains till a sufficient quantity for a Researchers be procured, which, in large dairies, happens generally once, but sometimes twice, in the week." In Ayshire whey is given to horses.

2578. Butter forming an important article of commerce as well as food, the legislature has passed various statutes respecting its package, weight, and sale. The principal are the 36th and 38th of Geo. III.

Sect. V. Process of Cheese-making.

2579. The production of cheese includes the making of rennet, the selection of a colouring matter, the setting of the curd, and the management of the cheese in the press.

2580. The milk fresh drawn from the cow is to be immediately strained into the dishes or shallow troughs, if these are used, in order to promote cooling, as the surface is a natural guard against fermentation. The same object may be attained by repeatedly drawing off the milk from the coolers, and pouring it back again.

2581. To understand what rennet is, and its uses, it is necessary to premise that milk is no sooner taken into the stomach, than it becomes curdled by the operation of the gastric juices, as every one who has seen much of infant children must have observed. What is called rennet is nothing more than the stomach of an animal in which the gastric juices are preserved by means of salt.

2582. The application of any kind of acid will cause milk to coagulate, as well as the infusion of several plants, as ladies' bedstraw (Galium verum), butterwort (Pinguicula vulgaris), and others. With the former plant the Jews coagulate the milk for all their cheese; the Mosaic law prohibiting them to mingle meat with milk, and rennet they consider as as a substitute.

2583. The mare or stomach of ruminating animals, which admit of obtaining the gastric juice in a less mixed state than those of other, and chiefly of a young calf that has been killed for the digestion is perfect, is almost universally preserved for this purpose. This bag or stomach is divided into different parts, each with a different method, described by Marshal in his Rural Economy of Norfolk, is considered as one of the best. "Take a calf's bag, maw, or stomach; and having taken out the curd contained therein, wash it clean, and salt it thoroughly, and hang it out, leaving a white coat of salt on it. Then take it to the press; when the butter is taken from the press, the curd will thrive as well as it, after the expression of the butter. The whey is put into a brass pan and boiled, and afterwards set in pans or jars, where it remains till a sufficient quantity for a Researchers be procured, which, in large dairies, happens generally once, but sometimes twice, in the week." In Ayshire whey is given to horses.

2584. In order to prepare this rennet for use, Marshal gives the following method. Take a bag filled with fresh and sound leaves of the leaves of the dog-rose, and the like quantity of fresh and sound leaves of other shrubs, such as the bramble leaves; boil them in a gallon of water, with three or four handfulls of salt, about a quarter of an hour, strain off the liquor, and, having let it stand perfectly cool, put it into a curd, and add to it the maw, prepared as above; if properly done, the result is a good substance, stuck round with a 'pint,' which is a measure of cheese, which give the rennet an agreeable flavour.

2585. The strength of the rennet thus prepared will increase in proportion to the length of time during which the bag remains in the liquor; the quantity to be used for the curd of cheese to coagulate milk can, throughout the whole process of preparing and preserving rennet, too much attention cannot be given to its clean-

1013
liness and sweetness; for if it be kept too long, so as to become foul or tainted, the cheese will invariably become affected by it, and will prove unfit for use.

7016. The rennet.* A small quantity of the muriatic acid is used instead of rennet; and it is the use of this article which gives to the Dutch cheese that pungent relish which induces so many persons to prefer it.

7017. Colouring matter. As cheese in its native state, that is, such as is well manufactured, being put together in proper time, the milk being of a proper degree of warmth, and in all other respects properly pressed, salted, and dried, is uniformly of a bright yellow cast, the idea of excellence is generally attached to cheese of such a colour. Hence it has become necessary for the dairyman, who would dispose of his cheese to advantage, to impart a light yellow orange colour to it by artificial means.

7018. Tannin, marigold, hawthorn buds, and other vegetables, were formerly employed for this purpose; but these have long since been rejected for the Spanish Arnotto, which is unquestionably the best ingredient of the kind that can be used for the colouring of cheese. It is a preparation of the resin or gum of a tree from which is extracted a substance similar to tannin (q. v.), which, when put upon the surface of the milk, the seeds of this tree, is suspended in hot water, and allowed to subside, and when dry, is formed into cakes or balls, which are further set aside, until they become completely dry and firm. One ounce of this substance, when genuine, will be sufficient to colour an hundred weight of cheese; and in the case of milk of an inferior quality, one ounce of it will be sufficient to colour a cheese of sixty pounds weight. The usual mode of applying the arnotto is to dip a piece, of the requisite size and weight, in a bowl of milk, and rub it on a smooth stone until the milk assume a deep red colour. This infusion is to be added to the milk, of which cheese is intended to be made, in such a quantity as will impart to the whole a bright orange colour, which will become the deeper in proportion to the age of the cheese. The mixing of the arnotto in no respect affects either its taste or smell.

7019. In the county of Cheshire, however, a somewhat different practice obtains. There, when the colouring matter is wanted, it is usual to tie up as much of the substance as may be deemed sufficient in a linen bag; putting it into half a pint of warm water, to let it stand over night. In the morning, immediately before the milk is coagulated, the whole of the water in which the bag is placed is mixed with the milk; the bagbeing put upon the water, and the water kept boiling, the bag is soon renewed, and the mixture placed in a vessel, and the whole is heated to great a distance; so that if rennet be put to it in this state, the curd, instead of coming in one or two hours, will require three, four, or five hours, and will be so spongy, tough, and in every respect so improveed, that the coagulation may be fixed at any time, being confined to the press, it will have no split, and be good for little. Whenever, therefore, cows are discovered to be in this state, which perhaps can scarcely be avoided during very hot weather, where cows are pastured abroad, in the open fields, over hills, or where the ground is not withered, or during the height of fresh spring water to the milk as soon as it is brought into the dairy. The quantity to be mixed, in order to impart the proper degree of heat, can in this case only be regulated by experience and the use of the thermometer. The effect of the water thus added will, in both cases, be to make the rennet take effect much sooner, and consequently to accelerate the coagulation of the milk.

7020. The proportion of rennet and time requisite for coagulation have been already mentioned (7045. 7046.): too much rennet ought not to be put in, otherwise the cheese will be ready to heave, as well as become rank and strong; the same effects will also be produced if the rennet is made with bad or foul materials, or if it be too strong to operate in the given time (two hours). During the process, the milk ought to be covered so as not to lose more than five or seven degrees of its original heat. One or two handfuls of salt added previously to mixing the rennet will promote coagulation. Some put in a bowl, which is of the ancient custum, and in London rather than in Kent. When the curd has sunk to the bottom of the vessel, the cheese is taken off by the hand, or by means of a skimming-dish; another quarter of an hour should be allowed for the curd to settle, drain, and air; and this process prevents the fat from being squeezed out through the fingers, and of course contributes to improve the quality of the cheese. Sometimes, in addition to the skimming-dish, a semicircular board and weight, adapted to the size of the tub, are employed. The curd is then free from the separation of the whey, and pressure is again applied till it be wholly drawn off. Great attention is re- quisite in conducting this part of the business; and if any particles of slip curd should be seen floating in the whey, it ought to be carefully laded off with the whey; as it will not incorporate with the solid curd. If any curd is found in the cheese, and if the whey be of a sounds, the whey will have a green colour, when loaded or pressed out, it is a certain criterion that the curd has been properly formed: but if it be of a white colour, it is equally certain that the coagulation is imperfect. This article will be of little value, and kind of little value, and be only thrown away. In the counties of Norfolk and Suffolk, the cheese manufacturers have recourse to a somewhat different method for extracting the whey, which is worthy of notice: when they think the milk sufficiently coagulated, they lay a strainer in a basin, of the proper size for the purpose; into which they put the curd, and set it to the county of Cheshire; in Cheshire, the whey will a quick curd. When the milk is sufficiently drained, it is put into two or three separate vessels, and is broken with the hand as small as
possible. During this part of the process salt is scattered over the curd, and intimately mixed with it; the proportion, however, has not been correctly ascertained, and is regulated by experience.

7054. Management in the press. The breaking and salting completed, a cloth is spread over the cheese vat, and the broken curd being packed into it, and covered up with the cloth, a smooth round board is laid over the vat, which is usually filled to the height of one inch above the brim, to prevent the curd from shrinking below its sides, when the whey is squeezed out.

7055. The whole is then put into a press for two hours, and as it is of the utmost importance that every drop of whey should be expressed, skewers are driven through the holes in the bottom part of the vat to facilitate its escape. The two hours expired, the cheese is taken out and put into a vessel of warm or hot whey for an hour or two, in order to harden its skin. On taking the cheese out of the whey it is wiped dry, and when it has become cool, is wiped in a clean dry cloth, of a finer texture, and again submitted to the press for six or eight hours. The cheese is now turned a second time, and is taken to the salting room, where it is rubbed on each side with salt; after which it is wrapped in another dry cloth, of a finer texture than either of the preceding cloths, and is again pressed for twelve or fourteen hours a day, being laid upon a dry bed of bran or straw every day. In the salting-room cheese should be kept warm until it has had a sweat, or has become regularly dry and somewhat stiff; as it is warmth that ripens cheese, improves its colour, and causes it when cut to have a flaky appearance, which is the surest sign of superior excellence.

7056. Management in the cheese-room. After the processes of salting and drying are completed, the cheeses are deposited in the cheese-room or loft, which should be airy and dry; but on no account should hard and soft cheeses be placed in the same room, for the dampness or moisture arising from the latter will cause the hard cheese to chill, become thick coated, and often spotted. Throughout the whole process of cheese-making, the minutest attention will be requisite; for if the whey be imperfectly expressed, or the rennet be impure, or the cheese be not sufficiently salted, it will become rank and pungent. For this defect there is no remedy. The imperfect separation of the whey will cause the cheese to cave in or swell, as well as to run out at the sides.

7057. In order to prevent as well as to stop this heaving, the cheese must be laid in a moderately cool and dry place, and be turned regularly every day. If the heaving be very considerable, the cheese must be pricked on both sides in several places, particularly where it is most elevated, by thrusting a skewer into it; but by pricking, the whey will be altogether prevented, a passage will be given to the confined air, the heaving or swelling will consequently be considerably reduced, and the cavities of the cheese will be less offensive to the eye. Another remedy for heaving in cheese consist in applying a composition of milk and ice, which is vended in the shops under the name of chertopatox. It is prepared by mixing one pound of salt petre with half an ounce of whole ice of bole amaricous thoroughly together, and reducing them to a very fine powder. About a quarter of an ounce of this is to be rubbed on a cheese, when a second and third time into the press, half on each side of the cheese at two different meals, before and after salting. This preparation prevents the cheese may be penetrated with air, which is so very binding, and sometimes proves serviceable, but the nitre is apt to impart an acid taste; and if too much be applied, and the cheese should be exposed to too great heat, the quantity of air already confined in it will be increased; hence the cheese is much more than it would if no powder had been rubbed in. The greatest care, therefore, will be necessary whenever this remedy is adopted.

7058. Hard and spoilt cheese may be restored in the following manner: take four ounces of pearlash, and pour sweet white wine over it, until the mixture ceases to effervescence. Filter the solution, dip into it clean linen cloths, cover the cheese with the same, and put the whole in a cool place, or dry cellar. Repeat this process every day, at the same time turning the cheese, and, if necessary, continue it for several weeks. Thus the hardest and most insipid cheese, it is affirmed, has frequently recovered its former flavour.

Sect. VI. Catalogue of the different Sorts of Cheeses and other Preparations made from Milk.

7059. Of cheeses, we shall first enumerate the British sorts, and next those peculiar to foreign countries: the description of each will be such as to enable any ingenious dairyist to imitate them.

7060. The brick-hot cheese is so named from the form of the mould; it is formed of new milk and cream in the proportion of two gallons of the former to a quart of the latter. It is principally made in Wiltshire, in the month of September, and should not be cut until it is twelve months old.

7061. Cheddar cheese, so named from the vale of that name in Sommersetshire, where it is exclusively made. It is made in cheeses about the size of each, which have a spongy appearance, and the eyes are filled with a limpid and rich, but not rancid oil.

7062. Cheshire cheese is in universal esteem; it is made from the whole of the milk and cream, the morning milk being mixed with that of the preceding evening, previously warmed. The general weight is sixty pounds each cheese.

7063. Dunlop cheese so called from its having been first brought to the Glasgow market by a carrier who lived in the parish of Dunlop, in Ayrshire, it has been made in the district of Cunningham in Ayrshire, and scarcely surpassed in England. According to Aiton, it is milder in its taste, and fatter, than any English cheese whatever. The following directions are from this author's Dairy Husbandry.

7064. When as many cows are kept on one farm as that their milk, milk form a cheese of any tolerable size, every time they are milked (before a day), the milk, as it comes from the cows, is passed through a sieve (trombina) or a net) to remove impurities into a horn vat, and when the milk is warmed, it is for several hours. As milk requires to be coagulated as nearly as possible at the temperature of animal blood (sanguis), the cream (from the milk) is allowed to separate, so that the milk and the cream (from the cream) is drawn from the vat, passed through the sieve, and the curd vat; and the cold milk from which the cream has been taken, is poured into the gourd; the temperature as the whole mass is allowed to cool in order to the mixture, and the whole is coagulated by means of rennet carefully mixed with the milk. The cream is put into the curd-vat, the milk in the vat, being heated by raising the temperature of the whole skinned milk is heated as much as to raise the whole to near animal heat. The utmost care is always taken to keep the milk in all stages of the operation free, not only from every admixture of impure, but also from being hurt by foul air arising from acidity in any milk substance, putrid water, the
PRACTICE in agriculture. Part III.

starch of the barley, oatmeal, or any other substance; and likewise to prevent the milk from becoming sour, when it happens to be exposed to the sun, it should be covered, and care should be taken to prevent the formation of curd and acid by the action of the sun. The temperature at which the milk is kept from the time it is drawn from the cows till it is finally used as curd, and should be carefully attended to. The milk, when taken from the cows, should be at a temperature no lower than 58° R. Fahrenheit's scale; or, cool, and should be kept cool, or even cold, until it is desired to use it. If the milk is kept too long at a much higher temperature than 58° R. Fahrenheit's scale, it will not properly curdle the cream, and the cream will become thick and sour. When milk is kept in a room where the air is free from iron cinders, the milk will cool in them much sooner than in the wooden dairies formerly in use for that purpose. If the milk be kept at a temperature nearly the same as that of the room in which it is kept, the cream will not coagulate, and the milk will soon become sour, and acquire a bad habit. If it is not brought to a temperature of 58° R. Fahrenheit's scale in a short time, the milk will acquire an impure and unpleasant taste. When the milk cannot be cooled in a short time, the cream and curd cannot be ever well tasted.

The milk should not be congealed at nearly its natural heat when drawn from the cow, or from 90 to 95 degrees of temperature, and for that purpose, a thermometer ought to be used in the morning, and sometimes in the afternoon. The thermometer should be made, and the cream collected, is, and should be very cold, and much better, much warmer the curd is tough, hard, and too adhesive; much of the butter curd not being curdled, and goes off white, and that the cheese becomes hard, dry, tough, and tasteless; and if the milk is too cold, the butter curd is coarse, very wet, does not part with the serum, and the cream continues to be so soft that it is difficult to separate them, and when the utensils are taken to extract the whey, and to give it solidity and firmness, putting holes, which in dairy language, are called pores, or springs, frequently break out on the cheese; and it is always soft, tough, and of an insipid taste.

5. The curd is broken, in order to let the serum or whey be separated and taken away from it; and is done by forcing it forward, by making cross-score with a knife or thin piece of wood, at about one or two inches distance, and inserting the knife or other at right angles in the curd. This is done more or less closely after some of the whey has been discharged. But others break the whole curd at once, with a sharp knife, or prong, and the whey, and keeping the hands off, until the curd is more or less completely broken. By the first method mentioned, the whey does not come off the curd so well, but the curd is more or less completely broken, and the curd is more or less timely broken.

6. Milk and milk cheese have been formed at a proper temperature, neither too cold or too hot, breaking the curd minutely, but generally broken very coarsely for the purpose.

But the whey is a little too white at first, that is soon over; it comes off abundantly pure in a few minutes after; and it does not properly curdle, if it is not sufficiently broken. The advantage of a speedy discharge of the whey is, it saves time, and prevents the curd from becoming too cool and acquiring any bad taste or flavour which it often contracts with being long kept in an insipid state.

7. The milk has been either too cold or too hot when congealed, I would recommend breaking the curd as slightly and evenly as possible, to the best of your power, and then the complete breaking at first aids to that evil, and brings off still more of the ed, substance from the curd, to which, in the production of the cheese, attention is too little paid, and the curd is much more tender and adhesive. When the milk has been too hot, the curd is so soft that it will not be broken in the curd by the curd and placed in the chest with a slice of white bread, and kept in an insipid state.

8. When the whey has been congealed a little, it is cut with the cheese knife, as it is called, and the curd is broken as little as possible with the hand, in order to facilitate the separation of the whey from the curd, and put under the cheese knife.

9. All these operations ought to be carried out with the least possible delay, and yet without precipitation. The sooner the whey is drawn off, the sooner the curd will be formed, the quicker the coagulation of the milk, and the sooner the cheese is formed, the sooner it will be ready for maturing. But if the curd is soft, from being set too cool, it requires much longer to get into cheese than if it were much of the curd and of the fat would go off with the whey. And when the curd has been formed, in that case the whey is a much more disagreeable matter, Precipitation, or handling the curd too roughly, would add to its toughness, and expel still more of the whey agreeable to the fat, and as has been already mentioned, hot water or why should be put on the curd when it is soft and cold; and to put hot water on it would be much more expensive, both in waste of salt, in apparatus, and in labour. The greatest defect I can perceive in the salt- ing in Scotland, is that the salt is generally applied to the cheese merely, and not to the whey, whereas it ought to be thoroughly regulated. Half an ounce of salt to every English pound of cheese, or at most thirteen ounces to twenty-four pounds. Enough, the cheese dry, tough and hard, and if a sufficient quantity is not given, the cheese will be too small and insufficient.

576. Cheeses made in Scotland are never washed or greased with water, and although the whey is sometimes nearly cleared from the grease internally, and not on the outside.

577. When the cheese in Scotland is ultimately taken from the cheese-press, it is well at least two or three days from the time they were first placed under it, they are exposed for a day or two, before they are put to dry, which is not to excite sweating, but merely to dry them a little before they are pressed; and if the sun is hot, or if it is dry or drought is admitted. While they remain in the kitchen, they are turned over three or four times; or more often, if the whey be pressed, and then, if it be dried, they are laid up on the shelves of the store, where they are turned over once every day, before they are hung in the barn, or sitting in the shelves during the summer, or left on the shelves of the cheese, that is to say, when they are hung in the barn, and carried to the store.

578. Cheese made for cheese in Scotland are in proportion to the size of the dairy, generally a small place adjoining the milk-house, or barn of a farm or other place, where the manufacture is carried on, with as many sheds or houses as the cheese made for the season, where no particular place is prepared, the milk, when it is taken from the cows, and is kept in the barn, which is generally a very little, and very irregular, and very small, and no partial fermentation is excited, but the cheese preserved so well.

579. On the comparative taste of the Scots and English cheese it may not be improper to mention, that the differences in the taste, not only of cheeses made in different dairies, at the different seasons of the year, stages of the country, but the variation of the climate, but there is also such a diversity in the taste of the consumers, that it is impossible to say, which is the best, without the standard of perfection of the taste of cheese. The taste of man- kind is so far from this, so much so, that it is found necessary to bring forward both Scots and English cheeses, of different sorts and ages, some round and others square, is not a sentiment the best, and does not agree with the Scots.
Cottage cheese, which, from its peculiar richness and flavour, has been called the Parmesan of England, is made in the following manner:—The night's cream is put to the morning's milk with the rennet, which, being sprinkled, it is not broken as is usual with other cheese, but is taken out whole, and put into a vat to drain gradually; while draining, it is gently pressed till it becomes firm and dry, and when it is placed in a vat, a box made exactly to fit it; as it is so extremely rich, that without this precaution it would be impossible to carry it about, and break it, is kept on dry boards, and turned daily, with cloth binders round it, which are tightened as occasion requires. After four or five days the cheese is taken out of the box, and put round with cloth till it acquires sufficient firmness to support itself: when these cloths are removed, each cheese is brushed once every day for two or three months, and if the weather be moist, twice every day. In a similar manner, and in a similar time, when the milk is putrid, it is frequently placed to place the cheeses in buckets, which are covered over with horse-dung. Wine is also reputed to be added to the curd, in order to accelerates the ripening of the cheese.

7856. Cottenham cheese, from the town of that name in Cambridgeshire, is a thicker kind of cream cheese than the Stilton; its superior delicacy and flavour are attributed to the fragrant nature of the herbage on the commons on which the cows are pastured, and, according to Professor Martyr, to the prevalence of P. a. aquatica and P. palustris.

7857. Suffolk, or skim cheese, is made of skimmed milk; it forms a part of every ship's stores, not being so much affected by heat as richer cheese, nor so liable to decay in long voyages.

7858. Parmesan cheese, made of unskimmed milk: sometimes a part of the quantity of skimmed milk is added. In some dairies it is manufactured in winter as well as summer; in the former case it is liable to become scurfy and white coated; the last of which defects is frequently concealed by a coat of red paint.

7859. (Of foreign cheeses, the most common is the Dutch cheese; this is prepared much in the same manner as the Cheshire cheese, excepting that muriatic acid is used instead of rennet, which renders it pungent, and preserves it from mites; that of Gouda is preferred.

7861. Parmesan cheese (formaggio di grana, cheese used in a granular form) is made in the Duchy of Parma. It was formerly supposed to be made from the milk of goats, but it is merely a skim-milk cheese, the curd hardened by heat, well salted, pressed, and dried, kept, and rich in flavour from the rich herbage of the meadows of the Po, where the cows are pastured.

7862. The process, according to Prince, (Both Papers, vol. viii.) is as follows:—The evening's milk, after having been skimmed in the morning, and standing till ten o'clock, and the morning's milk skimmed about two hours after it is drawn from the cow, are mixed together. The mixture is then suspended in the contents of a copper vessel covered over with a wooden lid (fig. 43.); the vessel is then put in, and the copper being removed from the fire, the vessel is tightly closed. The mixture is then worked with a stick till it is reduced to a small grain. The whole then being removed to a vessel, the curd is again turned over the fire, and its contents being well boiled, the vessel is covered with a lid (fig. 44.) to impart colour, the whole being all the while well stirred, and the superintendent examining it from time to time with his finger in the thickened liquid, till it is boiled down to a jelly; when the curd shall have become sufficiently solid. When this is the case, the curdure is removed from the fire, and the curd allowed to subsidize; three fourths of the whey is then drawn off, water poured round the bottom of the cauldron outside its curb, so as to admit of a cloth being passed below the curb, which is thus thrown up and placed in a tub to cool. When drained, it is put into a wooden hoop, and about half a hundred weight laid on it for half an hour; the cloth is then removed, and the cheese being replaced in the hoop is laid on a shelf; here it remains five or six days. Then, having been sprinkled, it is covered with salt, this sprinkling is repeated every second day for about thirty days. It is then allowed to stand about forty or fifty-five days if it be winter, after which no further attention is required. Then, the cheese is taken out of the hoop, which has been kept for three or four years, but none is ever kept more than six months. A short distance from a canals of fifteen to thirty-three miles from Milan, is called Cagliari Journey in Conca, Nov., in which the-cheese is manufactured. The process is there carried on in conformity with what is above stated.

7863. Swiss cheese is of several varieties, mostly of skimmed or partially skimmed milk, and manufactured like the Parmesan. Its varied and rich flavour is more owing to the herbage of the pastures than to the mode of making; and some sorts, as the Gruyère; so called from the bailiwick of that name in the canton of Fribourg, are flavoured by the dried herb of Melibechus officinalis (fig. 43.) in powder. Gruyère cheese weighs from forty to sixty pounds each, and are packed in casks containing ten cheeses each, and exported to the most distant countries. This cheese requires to be kept in a damp place, and closely covered, and only be washed with white wine, to preserve it from the depredations of insects. Neuchâtel is celebrated for a very fine sort of cheese made there, which, in shape, resembles a wash-hand ball.

7864. Westphalia cheese is of the skim-milk kind, and of a different character from any of those hitherto described. It is made of the milk till the latter is dried, kept, and dried, removed, and the milk placed near a fire spontaneously to coagulate. The curd is then put into a coarse bag, and, loaded with ponderous stones to express the whey: in this dry state it is rubbed between the hands, crumbled into an empty clean milk vat, where it remains from three to eight days, according to the season. During this part of the process, the cheese is continually rubbed afterboad, the whey, which is likely to cause the curd undergoes the putrid fermentation, and acquires a coat or skin on the top, before it is taken out of the vessel, and kneaded into balls or cylinders, with the addition of a considerable portion of carraways, salt, and pepper, the crusts of pounds pepper and salt; and dried, till the third part of fresh curds, thirds crumbled into small pieces, is superadded, to prevent or correct its putrid tendency. As the balls or cheeses do not exceed three or four ounces each in weight, they soon dry in the open air, and are then fit for use. When nearly dry they are sometimes, and are then suspended in a wood-fires; in this state, for several weeks or months; but both their taste and flavour are said to be remarkably improved, whether kept in a dry air, or subjected to the action of smoke. This sort of cheese M. Hochheimer, who describes it, affirms to be preferable to the Dutch, Swiss, and even Parmesan cheese common.

7865. Blue milk cheese is made in the neighbourhood of Edinburgh, by Mr. Johnston, of Hill House. It is similar to the Stilton, to which it is said to be not inferior. Mr. Johnston never puts his curd into a cheese mould, but, kneads it in a bag or net, in which it is suspended, and frequently shifted, till it is sufficiently dry and solid. The cheese are small; about five or six pounds each.
PRACTICE, lure The German, at usual shall efficacy with lorstorphin with cheese, simply with four and mentation a- milk must mtv 7102. has the twee) been in natural and with A made two to one of milk is poured; and the milk is heated and coagulated in order to make cheese, &c., or used as it is with other food; but if allowed to remain twenty or thirty hours, it becomes sour, coagulates spontaneously, the whey separates from the curd; and if it remain a certain period, generally three weeks longer, in a warm temperature, the viscous ferment takes place, an emulsion or a liquid, from which ancient spirit may be distilled, is produced.

1908. Buttermilk is that which remains in the churn after the butter has been taken off. When butter has been made from cream alone, it is seldom of much value; but where the whole milk has been churned, it is often very much improved by a few days and becomes hasty.

1909. In England it is chiefly given to pigs; but in Ireland it forms a very common diluter to porridge, potatoes, oat cakes, peas cakes, and other food of the labouring classes, and especially of the farm servants. In the Orkney Islands and other northern parts of Britain, as well as in Ireland, buttermilk is sometimes kept till it undergoes the yeas fermentation, when it is used to procure intoxication.

1910. Sour milk, Alton observes, requires considerable care in the manufacturing, and the use of the thermometer ought never to be dispensed with. When the temperature is carried on at a low temperature, the milk swells when agitated in the churn, appears of a white colour, throws up air bubbles, and makes, when agitated or churned, a rattling noise. But when it is in proper temperature the milk does not swell or rise in the churn, it is of a straw or cream colour, emits a much soeter sound, and does not cast up air bubbles with punctually as when churning. When milk is either overheated or churned too hastily, the butter is always soft and of a white colour. From two to three hours is a proper time for performing the operation of churning. In the manufacture of sour milk, and in every branch of dairy husbandry, the utmost attention to cleanliness is indispensably necessary. The milk should be kept in a warm place, and should not coagulate before it is churned; but if that souring is not natural, but brought on by any fouling in the vessels through which the milk passes, or by any sort of admixture, or even by the milk being kept in a damp place, in one too hot or too cold, or often by exposure to an inquiring atmosphere, the acidity will not be a natural one, nor the taste of the milk or butter agreeable, but acrid and unpleasant. Every vessel through which the milk passes must be as clean, and every part where it is kept before being churned must be as free from dampness, and every species of impurity or bad air, as if it were intended to keep the
Book VII. Varieties of Sheep.

1049

milk long sweet for skim-milk cheese. Buttermilk is used more or less by the labouring classes in all parts of Scotland, and in particular in the city of Glasgow; on the authority of the secretary to the Board of Agriculture, it is adjudged to the pigs in England; but in the western counties of Scotland, as well as in Ireland, it is used to a vast extent as human food. It is used as drink, and is certainly far superior to the miserable table-beer generally drank in England. It serves as kitchen to pottoage, bread, potatoes, &c.; and when a linen bag like a pillow-slip is filled with it, and hung up till the serum drops, and a small quantity of sweet cream is mixed with what remains in the bag, and a little sugar when it becomes requisite, it is placed on the table of a peer of the realm.

110. The method of making butter and buttermilk in Holland is somewhat different from the mode in the vicinity of Glasgow. After the milk is cold it is put into a pan or vat, and well stirred with a wooden spoon or ladle two or three times a day, to prevent the cream from separating from the milk; and this sort of stirring or partial churning is continued till the milk becomes so thick and clotted as readily as spoon stands erect in the milk; after which it is put into the churn, and beat or churned for one hour or so. Cold water is poured in, to help to collect the butter and separate the milk from it; after which the butter is washed in cold water. By this method the Hollanders imagine they obtain more butter from the milk than they can do any other way. They also say, that both the butter and buttermilk are better when made in that way than when churned as is done in England.

111. Whey, when new and of a pale green colour, forms an agreeable beverage, and with oatmeal makes an excellent gruel or porridge. Left till it gets sour, it undergoes the vinous fermentation required for buttermilk; and man, who in every state of civilisation feels the necessity of occasionally dissipating the cares of his mind, when he cannot find tobacco, opium, malt liquors, or ardent spirit, has recourse to sour whey.

chap. VI.

1112. The sheep is an inhabitant of every part of the globe, from Iceland to the regions of the torrid zone. The varieties of form and clothing necessary to fit it for existing in so many climates are of course numerous. In most of these countries it is cultivated for its wool or flesh, and in many for both; but it is most cultivated in Europe, and especially in France, Spain, and Britain. In the latter country its culture has attained an astonishing degree of perfection. Besides the O. Aries, or common sheep, there are three other species; the O. A'mmon or Siberian sheep, the Pudu or South American, and the Strepsiceros or Cretan sheep. By some these are considered mere varieties. The Cretan and Siberian are cultivated in Hungary and Siberia.

1113. The common sheep in a wild state prefer open plains, where they herd together in small flocks, and are in general active, swiftn, and easily frightened by dogs or men. When completely domesticated, the sheep appears as stupid as it is harmless. It is characterised by Buffon as one of the most timid, imbecile, and contemptible of quadrupeds. When sheep, however, have an extensive range of pasture, and are left in a considerable degree to depend on themselves for food and protection, they exhibit a more decided character. A ram has been seen in these circumstances to attack and beat off a large and formidable dog. Sheep display considerable sagacity in the selection of their food; and in the approach of storms they perceive the indications with accurate precision, and retire for shelter always to the spot which is best able to afford it. The sheep is more subject to disorders than any of the domesticated animals; giddiness, consumption, scab, drops, and worms frequently seizing upon and destroying it. That popularly called the rot is the most fatal, and arises from the consumption of animals called skulk worms, of the genus Fasciola, which inhabit the vessels of the liver. Other parasitic animals attack and injure them, as the hydrids within the skull, producing symptoms called sturdy, turn sick, staggers, &c. Frontal worms, deposited by the sheep fly, in some cases prove very injurious also.

1114. Of all the domestic animals of Britain, Brown observes, sheep are of the greatest consequence, both to the nation and to the farmer; because they can be reared in situations, and upon soils, where other animals would not live, and in general afford greater profit than can be obtained either from the rearing or feeding of cattle. The very fittest, shorn annually from their backs, is of itself a matter worthy of consideration, affording a partial return not to be obtained from any other kind of stock. Wool has long been a staple commodity of this island, giving bread to thousands who are employed in manufacturing it into numerous fabrics for home consumption and foreign exportation. In every point of view, sheep husbandry deserves to be esteemed as a chief branch of rural economy, and claims the utmost attention of agriculturists. For many years back it has been studied with a degree of diligence and assiduity not inferior to its merits; and the result has been, that this branch of rural management has reached a degree of perfection favourable to those who exercised it, and highly advantageous to the public.

sect. I. Varieties of Sheep.

7115. The varieties of the O. Aries, or common sheep, dispersed over the world are, according to Linnæus, the hornless, horned, blackfaced, Spanish, many-horned, African, Guinean, broad-tailed, fat-rumped, Bulgarian, long-tailed, Cape, bearded, and morvant; to which some add the Siberian sheep, cultivated in Asia, Barbary, and Corsica, and the Cretan sheep, which inhabits the Grecian islands, Hungary, and Austria; by Linnæus considered as species.

1116. The varieties of British sheep are so numerous that at first sight it appears almost impossible to reduce them into any regular classes. They may, however, be divided in two ways: first, as to the length of their wool; and secondly, as to the presence or absence of horns. A third classification might be made after the place or districts in which such species are supposed to abound, to be in greatest perfection, or to have originated.
7117. The long-wooled British sheep are chiefly the * Teeswater, the * old and * new Leicester, the * Devonshire nüts, Exmoor, and the Heath sheep.

7118. The short-wooled sheep are chiefly the Dorsetshire, * Hereford or Ryeland, the * South Down, the Norfolk, the * Cheviot, the * Shetland sheep, and the * Merinos.

7119. The hornless breeds are those in the above classes marked (*), the others have horns. These breeds, and their subvarieties, may be further arranged according as they are suited to arable or enclosed lands, and to open or mountainous districts.

7120. The sheep best suited to arable land, an eminent writer observes, in addition to such properties as are common in some degree to all the different breeds, must evidently be distinguished for their quietness and docility; habits which, though gradually acquired and established by means of careful treatment, are more obvious, and may be more certainly depended on in some breeds than in others. These properties are not only valuable for the sake of the fences by which the sheep are confined, but as a proof of the aptitude of the animals to acquire flesh in proportion to the food they consume.

7121. The long-wooled large breeds are those usually preferred on good grass-lands; they differ much in form and size, and in their fattening quality as well as in the weight of their fleeces. In some instances, with the Lincoln or old Leicesters in particular, wool seems to be an object paramount even to the carcass; with the breeders of the Leicesters, on the other hand, the carcass has always engaged the greatest attention: but neither form nor fleece, separately, is a legitimate ground of preference; the most valuable sheep being that which returns, for the food it consumes, the greatest marketable value of produce.

7122. The Lincolnshire, or old Leicestershire breed, have no horns, the face is white and the carcass long and thin; the ewes weighing from 14 to 20 lbs, and the three-year-old wethers from 20 to 30 lbs per quarter. They have thick, rough, white legs, bones large, pelts thick, and wool long, from ten to fourteen inches, weighing from 8 to 14 lbs. per fleece, and covering a slow-feeding, coarse-grained carcass of mutton. This kind of sheep cannot be made fat at an earlier age except upon the richest land, such as Romney Marsh, and the richest marshes of Lincolnshire; yet the prodigious weight of wool which is shorn from them every year, is an inducement to the occupiers of marsh-lands to give great prices to the breeders for their legs or yearlings; and though the buyers must keep them two years more, before they get them fit for market, they have three clips of wool in the mean time, which of itself pays them well in those rich marshes. Not only the midland counties, but also Yorkshire, Durham, and Northumberland, can send their long-wooled sheep to market at two years old, fatter in general than Lincolnshire can at three. Yet this breed, and its subvarieties, are spread throughout most of the English counties.

7123. The Teeswater sheep (fig. 882) differ from the Lincolnshire in their wool not being so long and heavy; in standing upon higher, though finer boned legs, supporting a thicker, firmer, heavier fleece, much finer upon their backs and sides; and in affording a fatter and finer grained carcass of mutton; the two-year-old wethers weighing from 25 to 35 lbs per quarter. Some particular ones, at four years old, have been fed to 55 lbs and upwards. There is little doubt that the Teeswater sheep were originally bred from the same stock as the Lincolnshire; but, by attending to size rather than to wool, and constantly pursuing that object, they have become a different variety of the same original breed. (Culley on Livestock, p. 122.) The present fashionable breed is considerably smaller than the original species; but they are still considerably larger and fuller of bone than the midland breed.

7124. The Dishley, or new Leicester breed (fig. 883), is distinguished from other long-wooled breeds by their clean heads, straight, broad, flat backs, round barrel-shaped bodies, very fine small bones, thin pelts, and inclination to make fat at an early age. This last property is much probably owing to the before-specified qualities, and which, from long experience and observation, there is reason to believe extends through the whole species of domestic animals. The Dishley breed is not only peculiar for its mutton being fat, but also for the fineness of the grain, and superior fatness, above all other large long-wooled sheep, so as to fetch nearly as good a price, in many markets, as the small Hampshire and short-wooled breeds. The weight of ewes, three or four years old, is from 18 to 25 lbs. a quarter, and of wethers, two years old, from 20 to 30 lbs. The wool, on an average, has white laces and legs, thick necks, narrow backs, and backbone high; the sides good, legs short, and the bones large; weight much the same as the Leicesters; wool heavier, but coarser. In the same county, there is a small breed of long-wooled sheep, known by the name of the Exmoor sheep, from the place where they chiefly breed. They are horned, with white faces and legs, and peculiarly delicate in bone, neck, and head; but the form of the carcass is not good, being narrow and flat-sided. The weight of the quarters, and of the fleece, about two thirds that of the former variety.

7125. The Devonshire Nuts (fig. 884) have white laces and legs, thick necks, narrow backs, and backbone high; the sides good, legs short, and the bones large; weight much the same as the Leicesters; wool heavier, but coarser. In the same county, there is a small breed of long-wooled sheep, known by the name of the Exmoor sheep, from the place where they chiefly breed. They are horned, with white faces and legs, and peculiarly delicate in bone, neck, and head; but the form of the carcass is not good, being narrow and flat-sided. The weight of the quarters, and of the fleece, about two thirds that of the former variety.

7126. The shorter-wooled varieties, and such as, from their size and form, seem well suited to hilly and inferior pastures, are also numerous. Generally speaking, they are too restless for enclosed arable land, on the one hand; and not sufficiently hardy for heathy mountainous districts, on the other. To this class belong the breeds of Dorset, Hereford, Sussex, Norfolk, and Cheviot.
VARIETIES OF SHEEP.

7127. The Dorsetshire sheep (fig. 885) are mostly horned, white faced, stand upon high small white legs, and are long and thin in the carcass. The wethers, three years and a half old, weigh from 16 to 20 lbs. a quarter. The wool is fine and short, from 3 to 4 lbs. a fleece. The mutton is fine grain and well flavoured. This breed has the peculiar property of producing lambs at almost any period of the year, even as early as September and October. They are particularly valued for supplying London and other markets with house lamb, which is brought to market by Christmas, or sooner if wanted, and after that a constant and regular supply is kept up all the winter.

7128. The Wiltshire sheep are a variety of this breed, which, by age and size, have got considerably more weight viz from 28 to 38 lbs. a quarter. These, in general, have no wool upon their bellies, which gives them a very uncomely appearance. The variations of this breed are spread through many of the southern counties as many in the face as in the fleece. The wool is shorter than the Dorsetshire breed, and yields every kind of grain. A cross between this breed and the merinos was extensively cultivated by the late Dr. Parry, of Bath, an eminent wool-grower. Natural improvement.

7130. The South Down sheep (fig. 887) are without horns: they have dark or black-grey faces and legs, fine bones, long small necks; are low before, high on the shoulder, and light in the fore quarter; the sides are good, and the loin tolerably broad, back-cloven, with a short, firm, and thick tail. The fleece is very fine, and of good quality. It is composed of similar fibres; it weighs from 21 to 38 lbs. The average weight of two years old wethers is about 18 lbs. per quarter, the mutton fine in the grain, and of an excellent texture. These sheep have been brought to a high state of improvement by Elman, of Glynd, and other intelligent breeders. They prevail in Sussex, on very dry chalky downs, producing short fine herbage. In the Norfolk sheep the face is black, horns large and spiral, the carcass short, and broad, long, thin, and weak, with a weak belly and thin fleece. They have fine, clean, small-boned legs, well covered with wool to the hough. The weight of the carcass, when fat, is from 12 to 18 lbs. per quarter; their fleece, which is of a medium length and fineness, weighs about 3 lbs on an average. Though these are the general characters of the pure Cheviot breed, many have grey or dun spots on their faces, and are not so heavy in weight as their black-faced neighbours. On the lower hills, at the extremity of the Cheviot range, they have been frequently crossed with the Leicesters, of which several flocks, originally Cheviot, have now a good deal both of the Cheviot and Leicesters in their make. All the same breed are a very good mountain stock, where the pasture is mostly green sward, or contains a large portion of that kind of herbage, which is the case of all the hills around Cheviot, where these sheep are bred. Large flocks of them have been sent to the Highlands of Scotland, where they have succeeded so well as to encourage the establishment of new colonies; yet they are by no means so hardy as the heath or black-faced kind, which they have, in many instances, supplanted.

7131. Of those races of sheep that range over the mountainous districts of Britain, the most numerous, and the one probably best adapted to such situations, is the heath breed, distinguished by their large spiral horns, black faces and legs, fine wild-looking eyes, and short, firm carcasses, covered with long, open, coarse shagged wool. Their weight is from 10 to 16 lbs. a quarter, and they carry from 3 to 4 lbs. of wool each. They are seldom fed until they are three, four, or five years old, when they fatten well, and give excellent mutton, and highly flavoured gravy. Different varieties of these sheep are to be found in all the western counties of England and Scotland, from Yorkshire northwards, and they want nothing but a fine fleece to render them the most valuable upland sheep in Britain.

7134. The Herdwick sheep (fig. 886) are peculiar to that rocky mountainous district at the head of the Duddon and Esk rivers, in the county of Cumberland. They are without horns, have speckled faces and legs, wool short, weighing from 2 to 3 lbs. per sheep, which, though coarser than that of any of the other short wool breeds, is yet much finer than the wool of the Cheviot breed. The mountains upon which the Herdwick are bred, and also the stock itself, have, in time immemorial, been farmed out to herds, and from this circumstance is derived the name of Herdwick.
variety, produced by peculiarities of situation, and different modes of management, and by occasional intermixture with other breeds. We may, therefore, distinguish the sheep of the mainland of Scotland from those of the Hebrides, and of the highlands and islands of Scotland.

7136. The Hebridean sheep is the smallest animal of its kind. It is of a thin, lank shape, and has usually straight shorn horns. The face and legs are white, the tail very short, and the wool of various colours; sometimes of a bluish grey, brown, and sometimes russet. They are very hardy, and sometimes infect in the fleece of one animal. Where the pasture and management are favourable, the wool is very fine, resembling in softness that of Shetland; but, in other parts of the same islands, the wool is stunted and coarse, the animal sickly and puny, and frequently carries four, or even six horns. The average weight of this poor breed, even when fat, is only 2 or 2½ lbs. per ewe, or nearly 6½ lbs., or about 4½ lbs. is often much less, varying between 2½ and 3½ lbs.; and the price of the animal's carcase, skin and all, is from 10s. to 14s. Fat wether sheep have been sold in the Long Island at 7s. a head, and ewes at 5s. or 6s. The quantity of wool which the fleece yields is equal to the weight of the carcase. It rarely exceeds one pound weight, and is often short of even half that quantity. The quality of the wool is different on different parts of the body; and inattention to separating the fine from the coarse, renders the cloth made in the Hebrides very unequal and precarious in its texture. The average value of a fleece of this aboriginal Hebridean breed is from 5s. to 7s. sterling. From this it appears that the breed in question has every chance of being speedily extirpated. (Macdonald's Report of the Hebrides, p. 447.)

7137. (If the Shetland sheep it would appear that there are two varieties, one of which is considered to be the native race, but is very fine wool, but the number of these is much diminished, and in some places they have been entirely supplanted by foreign breeds; the other variety carries coarse wool above, and fine wool below. They have three different successions of wool yearly, two of which resemble long hair more than wool, and are termed by the common people forse and scalda. When the wool begins to loosen in the roots, which generally happens about the mouth of February, the hairs, or scalda, spring up, and when the wool is carefully pulled off, the tough hairs continue fast until the new wool grows up about a quarter of an inch in length, then they gradually wear off; and when the new fleece has acquired about two months' growth, the rough hairs, termed by the farmers for pulling it arrives, when it is plucked off along with the wool, and separated from it, at dressing the fleece, by an operation called forcing. The scudia remains upon the skin of the animal as if it were a thick coat, a fence against the inclemency of the seasons, which provide nature has furnished for supplying the want of wool. The wool of the scudia is of various colours; the black, the white, the somnus, or brown, is very little inferior, though the white is certainly the most valuable for all the finer purposes in which coming wool can be used. (Sir John Sinclair on the different Breeds of Sheep, Sc. Appendix, No. 5. Account of the Thomas Shand, p. 78.) In the northern part of Kincardineshire, as well as in most other of the northern counties, there is still a remnant of this ancient race, distinguished by the yellow colour of the face and legs, and by the dishevelled texture of the fleece, which consists in part of coarse, and in part of remarkably fine wool. Their average weight is very little from seventy to ninety pounds a quarter, and the måke, or prime sheep, about 120 pounds. It is a well-esteemed and highly flavoured. (Kincardineshire Report, p. 365. Sup. E. Brit. art. Agr. 1756.) The Highland Society of Scotland have offered premiums for the improvement of this breed, and some experiments are now in progress on the different classes, and for a particular account of the breed itself, and its management, see Shirreff's Survey of Orkney and Shetland.

7138. The Spanish, or Merino breed, bears the finest wool of the sheep species; the males (fig. 889.) usually have horns of a middle size, but the females (fig. 890.) are frequently without horns; the faces and legs are white, the legs rather long, but the bones fine. The average weight per quarter of a tolerably fat ram is about seventeen pounds, and that of wens about eleven pounds.

7139. The shape of this race is from being perfect, according to the ideas of English breeders, with whom symmetry of proportion constitutes a principal criterion of excellence. The throatiness, or pouddle skin beneath the throat, which is usually accompanied with a sinking or hollow in the neck, pre- sent a most unattractive appearance, though it is much esteemed in Spain, as denoting both a tendency to fine wool, and a hearty fleece. The Spanish sheep are thick behind the shoulders; and Lord Somerville has proved that there is no reason to conclude that deformity in shape is, in any degree, necessary to the production of fine wool.

7140. The fleece of the Merino sheep weighs, upon an average, from three to five pounds; in colour, it is unlike that of any English breed; there is on the surface of the best Spanish fleeces a dark brown tinge, approaching almost to a black, which is formed by dust adhering to the greasy properties of its pile; and the contrast between this tinge and the rich white colour below, as well as that rosy hue of the skin which denotes high proof, at first sight excites much surprise. The harder the fleece, the more it resists any external pressure of the hand, the more close and fine will be the wool: here and there, indeed, a fine pile may be found in an open fleece, though this occurs but rarely. Nothing, however, has tended to render the Merino sheep more unsuitable to the English climate as a subject of wool, than the shortness of the fleece, which covers the head: it is of a very inferior quality, and classes with what is produced on the hind legs; on which account it does not sort with any of the three qualities, viz. ruminos, or prime; finos, or second best; and tosacos, the inferior sort; and, consequently, is never exported from Spain.

7141. Merinos were first brought by the English into England in 1774, and have since that time raised a great deal of interest before his Majesty's sales, which began in 1814: the desirable object of spreading them widely over the country, and subjecting them to the experiments of the most eminent professional breeders, has been greatly promoted by the institution of the Merino Society in 1814, to which belong many of the greatest landholders, and the most eminent breeders in the kingdom. For some years past, this breed has been on the decline. (Sup. E. Brit. art. Agr.) A considerable importation was made by Colonel Downie, of Paisley, which diversified the breed throughout the poorest parts of Scotland. See the Renfrewshire Survey. It is not known, however, that they have answered the expectations that were entertained of them, and that there are any flocks in the possession of rent-paying farmers. The only successful experiment in Scotland seems to have been that of the late Mr. Malcolm Lang, in the Orkney Islands; and it is not the pure race, but crosses into other breeds. See the General Report of Scotland, vol. iii.

Sect. II. Criteria of Properties in Sheep.

7142. The criteria of an excellent ram, as given by Culley, combines qualities which ought to be found in every breed of sheep cultivated for its flesh and wool. His head should be fine and small; his nostrils wide and expanded; his eyes prominent, rather bold or daring; ears thin, his collar full from his breast and shoulders, but tapering gradually all the way to where the neck and head join, which should be very
Book VII. BREEDING OF SHEEP.

1053

true and graceful, being perfectly free from any coarse hair or hanging down; the shoulders broad and full, and the neck short and strong, the collar forward, and the chin back, with the nose, or, if the least hollow in either place; the mutton upon his arm or fore-thigh must come quite to the knee; his legs upright, with a clean fine bone, being equally clear from superuous skin and coarse hairy wool, from the knee and houghs; and healthy sheep, who are broad and well formed, for which the chin, and a proper girth or full and deep, and instead of a hollow behind the shoulders, that part, by some called the fore-flank, should be quite full; the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight, the quarters long and full, with a very short ribbed skin, and none over the bone nor out: his two height, if at the inside of the thighs, deep, wide, and full, which, with the broad breast, will keep his four legs open and upright; the whole body covered with a thin pelt, and that with fine, bright, soft wool.

He is, in short, a rather wild or coarse breed, a slight clearness in the eye; a florid ruddy colour on the inside of the eyelids, and what are termed the eyestriplings, as well as in the gums; a fastness in the teeth; a sweet fragrance in the breath; a dryness of the nose and eyes; breathing easy and regular; a coolness in the feet; dung properly formed, coat or fleece firmly attached to the skin, and unbroken; the skin exhibiting a florid red appearance, especially upon the brisket. Where there are discharges from the nose and eyes, it indicates their having taken cold, and should be attended to by putting them in dry sheltered situations. This is a necessary precaution also in bringing them from one situation to another when weather is changeable.

1744. The criteria of the age of sheep is the state of their teeth; by their having, in their second year, two broad teeth; in their third year, four broad teeth; in their fourth year, six broad teeth; and in their fifth year, eight broad teeth before. After which, none can tell how old a sheep is while their teeth remain, except by their being worn down. At the end of one year, rams, wethers, and all young sheep, lose the two fore-teeth of the lower jaw; and they are known to want the incise teeth in the upper jaw. At eighteen months, the two teeth joining to the former also fall out; and at three years, being all replaced, they are even and pretty white. But as these animals advance in age, the teeth become loose. This practice follows them as their very first year, and often at the birth, and continue to grow a ring annually to the last period of their lives.

1745. The different ages and conditions of sheep have different names in different districts. After being weaned, the ram, or wedder lamb, is sometimes termed hog, hogget, or tag, during the whole of the first year; and the female lamb, an ewe, or gimmer lamb, and ewe tag. The second year the wedder has the head and body of the ewe is called a hog, hogget, or two-toothed lamb; the third year, a sheep hog, or four-toothed wether; and a four-toothed ewe or thave. The fourth year, a six-toothed wether, or ewe; and in some places, from the time of lambing till that of selling, the males are called tup-lambs; and from that period, the males are termed, sheep, tup, and ewe-lams, thaves, and ewes. The males in the same year, the females in the same year, are called lambs, wedder lambs, wedder wethers, dunnions, wedders. Cranes also signify old ewes; and there are several other provincial names, which are explained in their proper places.

Sect. III. Breeding of Sheep.

1746. In the breeding of sheep a greater degree of perfection has been attained than in any other live stock; and in this branch, in particular, the breeders of England stand higher than those of any other country.

1747. Bakewell, by careful selection during several generations, raised his stock to a state of excellence, in regard to meat, at an early age with a moderate consumption of food, and with the smallest portion of offal, which has been with difficulty equalled, certainly has not been exceeded, by the most skilful of his successors. It is a striking instance of the division of labour and skill, that there are breeders who devote themselves entirely to the breeding of rams for the purpose of letting out on lease, and who, merely part of the labour of the country, rams were let out from 20. to 30. each; but so great has been the improvement since that period, that they are now let out to common graziers at from 1. to 10 guineas, and to breeders of rams at from 20l. to 500. guineas. The breeding ram is shown for hire at certain times and places, by means of a licence, or by the owners, who, as a matter of practice, would not choose to part with him, even for a season, ewes are sent to him to be covered at a certain price per head; superior animals of this class being very seldom sold altogether. Much as this mode of doing business has been reprobated as a monopoly, and much as there sometimes may be of deception in making up rams for those shows, all intelligent practical men must agree, that there can be no better method of remunerating eminent breeders, and of spreading their improvements most widely, in the shortest period, and at the least possible expense. A single ram thus communicates its valuable properties to a number of flocks, often in distant parts of the country, without distracting the attention of ordinary breeders from their other pursuits.

1748. The two methods of breeding common to all animals are also adopted in breeding sheep. Breeding from the same names, commonly called breeding in and in; and breeding from different races, generally called cross breeding. Bakewell, according to Sir J. Sebright (In improving the Breeds of domestic animals, &c., effected his improvements by breeding from the same family; but according to Hunt, who has written an able answer to Sir J. Sebright's pamphlet. A Letter, &c. to Sir J. Sebright, &c.), he has bred from the same family; it being out of his power to breed from different families of a race which he was at the time employed in forming, and cross breeding he did not approve of. Breeding in and in is so repugnant to human feeling, that it is difficult to avoid considering it an unwise practice; for it does not follow that a flock of sheep in a wild state must necessarily breed in the nearest relationships, as father and daughter; but it is more probable that remoter relationships would be chiefly bred from, as these must necessarily be much more numerous. In a flock of sheep, or a herd of savage men, springing each from one pair, every parent must necessarily have many more relations than the main he can have mothers or daughters.

1749. Breeding from different families of the same race is the more general and approved practice. When a number of families of any breed have been for some time established in a variety of situations and climates, each subjected to different soils and treatment, it is found advantageous to interchange the males, for the purpose of strengthening the excellence, or remedying the defects of each family. Of this advantage Bakewell could not avail himself; but it has been very generally attended to by his successors. Cursiter, for many years, at Bakewell, at the same time that other breeders were paying a liberal price for the use of his own, and the very same practice is followed by the most skilful breeders at present. In large concerns, two or more streams of blood may be kept distinct for several generations, and occasionally, mixed with the happiest effects, by a judicious breeder, without having recourse to other flocks. (Supp. E. Brit. art. Agr. 177.)
1750. In breeding from two distinct races, the object is to acquire new properties or remove defects. This being the case, it is evident that great variation is more likely to occur in breeding from the same race. The very distinction of breeds imparts a considerable difference among any in some unimportant respects; and although the desirable property be obtained, it may be accompanied by such others as are not so useful or advantageous. A case of this nature, destined to occupy a situation which had excluded that property from the breed with which it was first crossed, would not give rise to the object, and would not be advantageous, even if the progeny be a mongrel, not suited to the purposes of the farmer, or be fairly able to obtain a suitable property of swiftness to fatten, as is the case when Cheviot ewes are crossed with Leicesters and the progeny will not prosper on the hills pastures of their dams, and will be equally unprofitable on the better pastures of their sires. But the offspring of this cross succeeds well on those intermediate situations on the sides of the Cheviot hills, where the manufacture of horn is not rich, there is a portion of lowland for producing clover good and turnips.

1751. As general rules in crossing breeds, it is to be noticed that in every case where the enlargement of the object, the cross bred must be better fed than its smaller parent. The size of the parents should also be but little disproportioned at first; and when some increase has been produced, one or more crosses afterwards may raise the breed to the required size. With these precautions, there is little reason to fear disappointment, provided both parents are well formed. (General Report of Scotland, vol. i. p. 14.)

1752. The most advantageous and proper age for ewes taking the ram in the different breeds has not been fully shown; but from a year to a year and a half may be sufficient, according to the forwardness of the breed and the goodness of the keep. Some judge of this by the production of brand or sheep's teeth. It should not be done while too young in any case. Ewes commonly bring their first lamb when two years old; in the hilly and mountainous districts of Scotland commonly not for a year after. Of course, they are usually eighteen or nineteen months old when they take the ram, throughout all the lowland districts.

1753. In regard to the season of putting the rams to the ewes, it must be directed by the period at which the fall of the lambs may be most desirable, which must depend on the nature of the keep which the particular breed affords; but there is a general time of breeding the sheep in Perthshire, where the intention is suckling for house-lamb, in which case it should be much earlier, in order that the lambs may be sufficiently forward. But, by being kept very well, any of the breeds will take the ram at a much earlier period. Where the rams are young, the number of ewes should seldom exceed one in ten rams, but as the rams grow a great deal, at least as from one to two hundred; but letting them have too many may be cautiously avoided, as by means of the year and the season of the season the number of this breed may sustain great loss in the number of the lambs.

1754. With regard to the period of gestation, the ewe goes with lamb about the space of five months, consequently the most common lambing season is March, or the early part of April; but "it has been observed that in many of the more southern districts, where sheep-breeding is carried on to a considerable extent, some parts of the ewe-stock are put to the rams at much earlier periods, so as to lamb a month or six weeks sooner; this practice is attended with the advantage of situations where early grass-lamb is in great demand. It is usual for the rams to remain with the ewes for a month or six weeks, and in some cases longer, in order to complete the business of impregnation, which in some districts is accelerated by smearing the fore-lbows of the rams with some colouring substance."

1755. The practice of turning a number of rams among the flocks formerly adopted is highly approved, as tending to prevent the main object and injure the rams. A better way is to let each ram have a particular flock of ewes, and with such a choice stock of ewes, as a flock of eight, a ram goes to, and as they are served replacing them with others. By this means there is more certainty, and more ewes may be impregnated. In such sort of fine stock, it is likewise of great utility to keep the rams during the season in a high manner. In this view a little oats in the straw, or a mixture of barley and pea meal, are excellent. Where ewes are backward in taking the ram, the best means to be employed are those of good stimulating keep. The rams should always be continued with the ewes a sufficient length of time.

1756. The ewe will breed twice a year, if it be made a point to produce such an effect by attention and high keep; since she will receive the male indirectly at any season, and, like the rabbit, very soon after bringing forth. Lisle gives an instance of three of his ewes, well kept, lambing at Christmas, tattening of them on the Lady-day, and again, the flock being landed and the ewes fed with hay, one of these ewes was ready to receive a ram immediately after lambing, but brought the second time only single lambs, although of a breed that generally produces twins. There is no doubt but the sheep would produce young thrice a year were the bad practice not to which has been so currently recommended with the rabbit, of allowing the male immediate reversion; the way to turn the advantage to us, which is the advantage, is to let the ewes go out of the flock when the lambs are weaned, and to bring both ewes and lambs into the flock when they are ready to receive a ram, and so produce lambs four times a year, but it is not likely the practice of lambing in this way will ever be adopted except by the richest farmers; and the reason is that the sheep does not require with this advantage to be kept, and are generally ready to come in again to the flock."

1757. When ewes are in lamb they should be kept in the pastures, and as free from disturbance as possibly be, carefully attended to in order to prevent accidents which are liable to take place at this time, such as those of their being cast in the furnaces, &c. Where any of the ewes slip their lambs, it is advised by Lisle to place them in a stall, without heat, and there to keep them empty for some time, and to give them Richard's flour, and carnations, to be kept as well as the nature of the farm will admit, in order that there may be less loss at lambing-time from the ewes being stronger, and the lambs more healthy and better capable of contending with what difficulties they may pass through the season at which they may be dropped. The shepherd should at this period be particularly careful and attentive to their assistance who have the regard to the sucking of the lambs, and to see that the udders of the ewes are not diseased. His attendance will often be required in the night as well as the day. At this season covered sheep-folds are of great advantage in saving and protecting both ewes and their lambs.

1758. In respect to the number of lambs at a birth it is remarked by Lisle, that the ewe brings most commonly one, next in degree of frequency two, rarely from three to five lambs at a birth. This property of the ewe he says, in some districts, is, he observes, very specific; the Dorset sheep usually bearing twins, and the large polled Belgian sheep, with their descendants, the Teeswater, and our other polled breeds, and are able to bear more at a birth. Other breeds bring twins in the proportion of one third of the flock, which is supposed to depend considerably on good keep. A certain number of ewes per centum prove barren annually; the conditions of natural defect, and the circumstances of various other kinds of discernment, which are stated above, in the chapter of the natural state of body from poverty or neglect of the ram; in other words, want of system in the shepherd.

1759. The keep of sheep after lambing, where rich pastures or other kinds of grass lands cannot be raised, is best of turnip pastures of green hay, or green bunches of grass, to be purchased, and given them in a suitable manner; but where it can be done, it is always better to leave this sort of feed untouched till about the period of lambing, when it should be regularly supplied in proportion to the necessity there may be for it. The ewes also demand at this time much care to see that they are put upon a dry sheltered pasture, free from disturbance, and that neither they nor their lambs sustain injury from the too great
severity of the season. Whenever this is the case, they should be carefully removed into a proper degree of warmth and shelter till perfectly restored. It is likewise a necessary as well as useful practice, as they lamb down, to take them and their lambs away from the common stock, putting them into a piece of turnips or fresh dry pasture where there is shelter when necessary, as by this means much fewer lambs will be lost than otherwise.

It is also found that by a proper supply of turnips or other similar green food at this period, the milk of the ewes is much increased, and the growth of the lambs greatly promoted; which is of much future importance, as when they are stunted at this early period of their existence, they will be well afterwards to keep them, and they often come to the crop and preserved after grass, hay, straw, corn, and oil-cake are in some cases made use of in the winter support of sheep stock. With turnips, where the soil is not sufficiently dry to admit the sheep, it is the practice to draw them and give them to a sound firm pasture, that the ewes may be baited upon their turnips taken twice in the day as there may be occasion, care being taken that they are eaten up clean, the circumstance of their being thus eaten may serve as a guide to the farmer for the supply that may be daily necessary. In this way this sort of food will be consumed with the greatest economy. Where the land is perfectly dry, and the intention is to manoeuvre it for a grain crop, eating the turnips on the land, by means of portions hurdled off as wanted, is a good practice. With this sort of food, especially where it produces scouring in the ewes, green rouen hay, cut straw, or pease haulm should constantly be given, and also with rape, &c.

110. The castrating lambs may be performed any time from the age of a fortnight or three weeks to that of a month or six weeks, and in some districts it is deferred to a considerably later period. It is, however, the safest method to have it executed early, as there is less danger of too much inflammation taking place. But in all cases the lambs should be in a healthy state when it is done, as under any other circumstances they are liable to be destroyed by it. The operation is usually performed by the shepherd, by opening the scrotum or coil and drawing out the testicks with the spermatic cord. This he often does with his teeth in the young state of the animal; but where the operation is performed at a later period, it will be more advisable to have recourse to the Knife, the arteries being taken up and secured by means of ligatures, or the searing iron. The business, if possible, should be done in fine weather, when not too warm, and the gelded lambs be kept in a dry, sheltered, quiet situation for a few days, until the inflammation is gone off. If it should happen to be wet at that time, or should be advisable to have them under some sort of shelter where they can have room to move freely about.

111. The weaning of lambs should be effected when they are three or four months old, as about July; but it is done more early in some districts than others. A proper way to preserve or supply the ewes with milk, where there may be a good bite for the lambs to feed upon, should he had recourse to, as it is of much consequence that an ample provision of this sort be had, in order that the growth of this young stock may not suffer any check on being taken from the mother. Where they have been continued so long as to grade the lambs, little will be sustained in their separation if turned upon such good feed. Some advise clover in blossom as the most forcing sort of food in this intention, and with others saintoin is highly valued for the same purpose. When good feed is not provided of some of these kinds, the lambs should be fed on bran, and the milking of them is said to pitch them into perfect health. If this happens they never afterwards thrive so well, however good the management may be. With regard to the ewes, they should be removed to such distant pastures or other places as they may not be heard by the lamb, which would cause them to be disturbed in their feeding; and where the ewes sustain any injury from their milk, as by their udders swelling, it should be drawn once or twice, as this means bad consequences may be prevented; and as soon as the lambs have been removed, the ewes are returned upon the pastures destined for their summer support. There is, however, one caution to be attended to, and that is, to keep which is the first. They should be quite satisfied with food previously, that they may not be surfeited by too quick and full feeding, and may be as it is termed. Keeping them gently moving about the field has also been advised in this intention. In some places, where the lands are of the more poor kind, it is a custom to send the lambs to the more rich vale or marsh districts, to be brought forward in condition or fattened. In those cases where the lands of the male kind are reared on the home lands as wethers, they are usually restored to the flock in the latter end of the year, but which is not by any means a good practice, as they often suffer for want of proper keep in the winter, and lose what they had previously gained in growth and condition. A practice the reverse of this has long been in use among the store-masters of Scotland. They send their lambs, as soon as weaned, to some rough coarse pasture, often at a distance of several miles, where they remain for six or eight weeks. The opinion is that this renders them more hardy. Some say coarse grass fed on by lambs, as it is esteemed, the owner of the lamb paying a penny or three halfpence a week for each. The practice, it is believed, is not now so common as it has been.

SECT. IV. Rearing and general Management of Sheep.

1762. In the practice of sheep husbandry different systems are had recourse to, according to the extent and nature of the farms on which they are kept, and the methods of farming that are adopted on them; but under all circumstances the best sheep-masters constantly endeavour to preserve them in as good condition as possible at all seasons.

1763. With the pasture kinds of sheep this is particularly the case; and with the view of accomplishing it in the most complete manner, it is useful to divide them into different parcels or lots in respect to their ages and sorts, as by that practice they are kept with greater ease and convenience and benefit different kinds; as in this way there is not only less waste of food, but the animals thrive better, and the pastures are fed with much more ease. The advantage of this management has been fully experienced in many of the northern districts, which is that they usually divide their stock to keep, by sex, and the stock in a manner according to the circumstances; and in this method it appears not improbable that a much larger proportion of stock may be kept, and the sheep be preserved in a more healthy condition. With a breeding stock the sheep-masters must act according to his circumstances, situation, and capital which he possesses, either selling the sheep for money, or else keeping them on, but which may be shorn and sold as broad or fat wethers; the ewes being sold lean or in store condition, or fattened, as circumstances, profit, and convenience may point out.

1764. Another practice, but which requires much capital as well as care to be attended to, is to buy broad or fat wethers and ewes, especially where markets for their sale when fat are conveniently situated; or this system may be partially acted upon, varying the plan according to capital, circumstances, and the nature of the times. In which case, whenever store stock become extravagantly high, it is mostly a good way to sell.

1765. The sheep farming of the arable or low warm districts of the kingdom consequently differs in various particulars from that of the hilly and mountainous districts; we shall, therefore, first give a general view of the sheep management of arable lands, next of mountainous districts.

BOOK VII. REARING OF SHEEP.
SUBJECT. 1. Rearing and Management of Sheep on rich grass and arable lands.

7166. The most general sheep husbandry on rich lands, or where turnips and other green food is raised for winter consumption, is to combine the breeding and feeding branches, leaning to each according to the returns of profit.

7167. A method very common among arable farmers, and which is attended with the least trouble and hazard, is that of purchasing a store flock, as lambs, wethers, and what are termed cromes, or old ewes; some of the last sort often proving with lamb, may be fattened off with them to good account. It is like-wise observed that, ewes that are sown of in late spring, and join the couples, in which circumstances it is frequently a good practice to make annual purchases of them, in order to the fattening of both, and selling them in that state within the year. In the purchasing of sheep, which is often done from very distant fairs and markets, much care and circumstances is necessary, which a man of intention who are hereby the increased price of the sheep advantage, especially when at a considerable distance, may be derived by employing a salesman on the spot.

7168. The treatment of the lambs is the first consideration in the mixed sheep husbandry.

7169. Lambs are either suckled or fattened on grass, or sold in autumn as lean stock. With regard to those that have been suckled or fattened in the house, much attention is required to have them early, to their being well, regularly, and very cleanly kept and suckled, as well as to the ewes being of the right sort, and the best milkers that can be provided, and to their being fully supplied with food of the most nourishing and succulent kinds. Their tails and udders should have the wool well clipped away from them, in order that they may be preserved in a perfectly clean state. The lambs also require, especially towards the close of their fattening, to have regular supplies of barley, wheat, and peas-meal, ground together with some turnips from the beginning of May. When they are penned late in the evening, and which have been fattened on the best grass land will be ready to succeed them at the markets, in the spring and summer months, and these will be followed by the sale of the store lambs, at the different autumnal fairs.

7170. The selection or setting of the lamb stock is the first business of sheep management after the lambs have been weaned.

7171. It is generally performed in the month of July or August, at which period the fairs for the sale of lambs mostly take place. And as at this time the whole are collected together for drawing into different lots, it is a very suitable period for selecting or choosing those that are to supply such deficiencies in the breeding flocks. In his Calendar of Husbandry, Young has remarked, that in making this selection the farmer or his shepherd usually (whatever the breed may be) rejects all that manifest any departure from certain signs of the true breed; thus, in a Norfolk flock, a white leg, and a face not of a hue sufficiently dark, would be excluded, however well formed; in the same manner a white face on the South Downs; in Wiltshire, a black face would be an exclusion, or a horn that does not fall back; in Dorsetshire, a horn that does not project, &c.

7172. The selection of the grown stock generally takes place after the lambs are weaned, or, at all events, before tupping season, though wethers may be drawn out of the flock at any time. A certain number of old ewes or cromes are removed every year, and these as well as the wethers are fed off for the butcher, either on grass, artificial herbage, or roots, according to the situation and circumstances of the farm, and season of the year.

7173. The shearing of sheep is an annual operation, which includes several preparatory measures and after-processes. These are, washing, separation, cutting, clipping, marking, and tail-cutting.

7174. The proper time for clipping or shearing sheep must be directed by the state of the weather and the climate in the particular district, as by this means the danger of injury by cold from depriving the sheep of their coats at too early a season, and from heat by permitting them to continue on them too long, may be avoided in the best manner; but another circumstance that should likewise be attended to in this business, is that of the wool being fully grown or at the state of maturity; as where the clipping precedes that period, it is said in the Annals of Agriculture to be weak and scarcely capable of being spun, and if protracted later, it is yellow, felted, and of an imperfect nature. It has been stated, that for the most advantageous situations in the southern parts of the kingdom, the beginning or middle of June, when the weather is fine, may be in general the most proper; but in the more exposed districts in the northern parts of the island, the middle or latter end of the same month may be more suitable, provided the season be favourable. But with the fattening sheep in the enclosures, it will mostly be necessary to perform the work at an earlier period in every situation, as the great increase of heat from the setting in of the summer weather, added to the warmth of the fleece, becomes very oppressive and injurious to them in their feeding. There never can be any difficulty in ascertaining the proper time for shearing, because the separation of the old wool from the new is always distinctly marked in a thriving sheep; and this happens earlier or later according to the age and condition of the animal. Hence, from the beginning of May, or earlier, till the first week of July, shearing goes on in different districts; beginning with the fat lambs, and ending with the small nursing ewes of the Highland districts. From the middle of May to the middle of June is the busiest period.

7175. Sheep-shearing in Romney Marsh commences about midsummer, and finishes about the middle of July. Those who shear first think they escape the effects of the fly, and those that shear late apprehend the worst of a putrid weight in every fleece, by the increased perspiration of the sheep, if sheared in the heat of summer, the wool has not the condition which it afterwards acquires; but the hot weather occasions a good deal of trouble in detecting the fly. The lambs that are sold in Smithfield market are, we believe, sheared, or even shaved. All over the north of England, and throughout Scotland, lambs are never shorn. They lose their first fleece when about fifteen months old.

7176. Clipping off the coarse soiled wool about the thighs and docks, some weeks before the usual time of washing and clipping the sheep, is an excellent practice; as by this means the sheep are kept clean and cool when the season is hot, and with ewes the udders are prevented from becoming sore.

7177. In separating for the purpose of washing, the flock is brought to the side of the washing-pool, and there lambs and sheep of different kinds, fit to be washed, are put into separate fields; and such lambs as are too young to be clipped are not washed, but confined in a fold or enclosure of any kind, at such a distance from the washing place as that they may not disturb their mothers by their bleating. The object of washing is simply
to free the fleece from dust and dirt of various kinds. In Devonshire and Spain, the short-woolled sheep are not washed.

To perform the operation of washing, it was formerly the method, and it still exists in the north, to have the washers standing up to the breast in the water; but from the inconvenience and danger of it, the men requiring a large supply of spirituous liquors, and being liable to be attacked with colds, rheumatism, and other diseases, as well as being apt to despatch the work with too much expedition, so as to leave the wool insufficiently clean, it has been proposed by Young, in his Calendar, to roll off a portion of the water in a stream or pond (fig. 891), for the sheep to walk into by a sloping mouth at one end (a), and to walk out by another at the other end (b), with a depth sufficient at one part for them to swim; and to pave the whole: the breadth need not be more than six or seven feet. At one spot on each side of this passage, where the depth is just sufficient for the water to flow over the sheep's back, a cask or box (c), water tight, should be fixed, for a man to stand in dry; the sheep being in the water between them, they swim in perfection, and pushing them on, they swim through the deep part, and walk out at the other mouth, where a clean pen (d), or a very clean dry pasture, is ready to receive them; of course there is a bridge railway to the tubs, and a pen at the first mouth of the water (c), whence the sheep are turned into it, where they may be soaking for a few minutes before being driven to the washers. But other more cheap contrivances may be provided, where there is clean water at hand for the purposes.

After the sheep are washed, they should on no account be driven on dry or dusty roads; but should have a clean hard pasture for a few days, until they are perfectly dry and in a proper condition to be shorn.

The common method of catching the sheep, in order to lay it on its back to be shorn, is by the hinder leg, drawing the animal backward with a crook (fig. 892. a, b, c) to the adjacent shearing place; the hand holding the leg to be kept low, when at the place it is turned on its back; or they are moved bodily, or one hand placed on the neck, and another behind, and in that manner walked along: the first or common mode he thinks the most safe. Sheep fed on rich pastures, and fleshy, if handled hard and bruised, the parts are liable to fatal mortifications; an accident which often happens, on which accounts pens upon some lands are obliged to be lined with woollen, or many would die from bruises.

In performing the operation of shearing, the left side of the sheep is placed against the shearer's left leg, his left foot at the root of the sheep's tail, and his left knee at the sheep's left shoulder.

The process commences with the shears at the crown of the sheep's head, with a straight cut along to the loins, returning to the shoulder, and making a circular shear around the off side to the middle of the belly; the off hinder leg next: then the left hand holding the tail, a circular shear of the rump to the near back of the sheep's hind leg; the two fore feet are next taken in the left hand, the sheep raised, and the shears set in at the breast, when the remaining part of the belly is sheared round to the near stile; lastly, the operator kneeling down on his right knee, the sheep's neck being laid over his left thigh, he shears along the remaining side.

The method in Northumberland, introduced by the Messrs. Culley, is to begin at the back part of the head, in order to give room for the shears to make their way down the right side of the neck, to the middle of the breast. The man then sits down upon his right knee, laying the head of the sheep over his left knee bent, and beginning at the breast, clips the underside of the throat upwards to the left cheek; then takes off the back of the neck, and all the way down below the left shoulder. He then changes to the contrary side, and makes his way down to the open of the right flank. This done, he returns to the breast, and takes off the belly, after which it matters not which side he clips, because being able to clip with either hand, he meets his shear points exactly at the middle of the back, all the way, until he arrive at the thighs or legs. He then places the sheep on its left side, and putting his right foot over the neck, and the other forward to the undermost hind leg, clears the right side; then turning the sheep over, finishes the whole.

The fleece being removed, it wound up; that is, deprived of any clotted wool or dirty part, and lopped with the shorn side outwards, beginning at the breech and ending at the shoulders, where the next wool serves as a bandage.
PRACTICE and while ewe farm being ° pasture, or than for the open would, Captain described the November, ma]

7185. Marking is performed on each sheep about a week after the fleece is removed. The object is to identify the individuals as the property of the master. Sometimes initials are impressed, and at other times other marks. They are impressed by stamps, or merely chalked or painted on. A stamp dipped in warm tar is the most durable mode. Some place the mark on different parts of the sheep, according to its age; others cut the margin of the ears in different ways.

7186. Shortening the tails of the sheep is performed in almost all the sheep districts of the kingdom except in Dorsetshire, which seems to be a useful practice, especially with long-woolled sheep, in keeping the animals more clean behind, and of course less liable to be stricken with the fly.

7187. It has, however, been suggested in the ninth volume of Annals of Agriculture, that by this custom the tails might be rendered less liable to drive away the flies. The suggestions which would, however, seem to prove its being of advantage. There is much difference in the manner of performing the business in different districts in respect to the length, but four or five inches being left is quite sufficient. It is usual to cut a piece of the inner skin and to be well cleared from briers, as their coats are often injured by being torn by them. And all sorts of pernicious reptiles should be as much as possible destroyed, and removed from such land.

7188. The mode of pasturing sheep, or of feeding them on hebage or roots having been described when treating of these crops, the more general practices of rearing and management of lowland sheep husbandry may be considered as developed. Some peculiar practices and the mode of fattening lambs will be found in subsequent sections.

7189. The practice of giving salt to sheep deserves to be generally recommended. It is given in small troughs every day throughout the year, and in rainy weather twice a day, or under cover, that it may not be washed away. The practice is particularly recommended, when sheep are first put to turnips. A pound and a half salt for each sheep is generally allowed; but if it is an advantage, and at no danger, the reverse, will result from their having at all times as much as they will voluntarily take.

SUBJECT 2. Rearing and general Management of Sheep on Hilly and Mountainous Districts, or what is generally termed Store Sheep Husbandry.

7190. The best store farmers in Britain are unquestionably those on the Cheviot hills, which border the two kingdoms; and an account of their management may be considered as applicable to the mountainous districts of the whole kingdom. It is, indeed, applied by the migrations of the Cheviot and Teviotdale farmers, both in the North Highlands, on the Sutherland estate, and in Wales. No regular system of store farming, as observed by Napier (Treatise on Store Farming), appeared previously to his own; and accordingly from this work, and an excellent account published in the Supplement to the Encyclopædia Britannica, we have extracted what follows.

7191. A general idea of the extent and nature of a store farm may be obtained by referring to that of Thrillatan in Ettrick forest, a plan of which (fig. 883) is given by Captain Napier. It contains one thousand one hundred and fifty-one acres; of which one thousand four hundred and forty-five are in open hill pasture, seventy in plantation, forty in arable and meadow, about sixty in six enclosures, and the rest in shepherds' and other cottagers' houses, with their allowance of ground for a garden and cow. Well-trained and fine-souled ram, for most others is the number of stags, or stallions, employed for sheltering and feeding sheep during storms of snow, which are distributed over it; being fewer than thirty-seven. The advantages of these stews in districts where sheep are liable to be buried by snow Captain Napier considers very great, and to promote their more general introduction seems to have been one principal inducement for publishing his book. We shall recur to the subject in the following section, when treating of cotting, folding, housing, &c. In the mean time, we are informed that Captain Napier's round stews are not generally approved of, but that one is preferred which has four concave sides. See Forthofbra's Treatise on Store Farming, Edin. Svo, 1818.

7192. In the practice of store farming the rams are put to the ewes for the purpose of copulation in November, a little earlier or later, according to the prospect of spring food, but seldom before the eighth or tenth of that month. The number of rams required is more or less, according to the extent of the pasture, and their own age and condition. If the ewes are not spread over an extensive tract, one ram to sixty ewes is generally sufficient. It is usually thought advisable to separate the gimmers (sheep once sown) from the older ewes, and to send the rams to the latter eight or ten days before they are admitted to the former. Notwithstanding this precaution, which retards their lambing season till the spring is farther advanced, ewes which bring their first lamb when two years old, the common period on the best hill farms, are often very bad nurses, and in a late spring lose a great many of their lambs, unless they are put into good feeding with turnips before their lambing, and get early grass afterwards. This separation, and difference in the time of admitting the rams to the ewes and gimmers, should therefore be always attended to. When a farm under this description of stock has the convenience of a few good enclosures (as in Thrillatan farm for example), still more minute attention is paid by skilful managers. It is not sufficient that the rams are carefully selected from perhaps double the number of ewes which are drawn out and kept separate, and a ram appropriated to each lot as possesses the properties in form or fleece in which the ewes are deficient. In other cases, the best ram and the best lots of ewes are put together. When neither of these conditions can be adequately complied with, owing to the want of enclosures, it is the practice to send the best rams to the ewes for a few days at first, and those of an inferior descriptions afterwards. In every case, when the farmer employs rams of his own flock, he is careful to have a few of the best ewes covered by a well-fitted and fine-souled ram, for the purpose of obtaining a number of good ram-lambs, for preserving or improving the character of his stock.

7193. The stock through winter, in a mere breeding farm, consists of ewes and gimmers, which should have lambs in spring; ewe lambs or gimmers; and a few young and old rams. All these are sometimes altogether insufficient, and the farmers are precocious, and put on the farm early in autumn, and remove the lambs and rams as soon as possible. These are kept separate, and the ewe hogs are either put on rough pastures, which have been lightly stocked in the latter end of summer, or get a few turnips once a day, in addition to the remains of their summer pasturage. The most effectual preventive of the desolating distempers to which sheep of this age are liable is turnips; and though they should never taste them afterwards, a small quantity is frequently given them during their first winter. After the rams have been separated from the ewes, they are usually indulged with the same feeding as the hogs.
The ewes, during winter, are seldom allowed any other food than what their summer pasture affords, except that a small part of it may sometimes be but lightly eaten, and reserved as a resource against severe storms. When these occur, however, as they often do in the Cheviot district, there is little dependence on any other food than hay. When the snow is so deep as completely to cover the herbage, about two stones *anterior* of hay are allowed to a score of sheep daily, and it is laid down, morning and evening, in small parcels on any sheltered spot near the house, or under the shelter of *sedis* or clumps of trees, on different parts of the farm.

The ewes in March, at least the gimmers or young ewes, are commonly allowed a few turnips once a day, on farms on which there is any extent of arable land; which are either carted to their pastures, or eaten on the ground, by bringing the sheep to the turnip field through the night. A part of the field, in the latter case, is cut off by nets, or by hurdles, which enclose the sheep in the same way as if they were intended for fattening. When they are ready to drop their lambs, they are no longer kept on the turnip field, and get what turnips may be left on their pastures. But it is seldom that the turnips last so long, though it is desirable to have a few remaining to be given to the weakest ewes, or to such as have twins in a separate enclosure.

A few days before the time of lambing, the ewes are collected for the purpose of being underlocked. The sheep are raised upon their buttocks, their backs next to the operator, who then bends forward and plucks off the locks of wool growing on or near the udders, for the purpose of giving free access to the expected lambs. At the same time he ascertains the condition of the ewes, and marks such as do not appear to be in lamb, which may then be separated from the others. This operation is not without danger, and several premature births are usually the consequence. It is therefore not so general a practice as it was formerly, though still a common one on many, if not on most farms.

The separation of the hogs from the ewes, where these have been allowed to pasture promiscuously, should always take place at the commencement of the lambing season, and the lowest and finest part of the pasture be exclusively appropriated to the nursing ewes. On the Cheviot hills the hogs are generally pastured apart on the coarser herbage.

The lambing season commences with the first or second week of April, according to the time at which the rains were admitted; and such as have twins, generally lamb among the first of the flock. At this season, the most constant attention is indispensable on the part of the shepherd, both to the ewes in labour and to the newly dropped lambs. Though the Cheviot ewes are not so liable to losses in parturition as some larger breeds which are in higher condition, and though they make good nurses, unless they are very lean, and their food scanty, yet, among a large flock, there are always a number that need assistance in lambing, and in a late spring not a few who have not milk sufficient for their lambs, particularly among the gimmers or young ewes. A careful shepherd at this time always carries a bottle of milk along with him, which he drops from his own mouth into that of the lamb that may need it; brings the ewes that have little milk to a better pasture, or to turnips, and cordons such as have forsaken their lambs in a small pen, or barrack as it is called, temporarily erected in some part of the farm-steadin. The same confinement is necessary when it is wished to make a ewe that has lost her own lamb, nurse that of another ewe that has had twins, or that has perished in lambing, or is from any other cause incapable of rearing her lamb. The ewe, after being shut up a few hours with the strange lamb, usually admits it to the tent, and ever after treats it as her own; though sometimes a little deception is necessary, such as covering the stranger with the skin of her own lamb. At this important season, an enclosure of rich early grass, near the shepherd’s cottage, is of vast advantage. Thither he carries the ewes and twins,
such as have little milk; those that have been induced to adopt another's offspring; and, generally, all that need to be frequently inspected, and are in want of better treatment than the rest of the flock. (Supp. § 5.)

713. Castration is performed in the male lambs when a few days old, the ewe lambs are never spayed; milk, ether is chosen, and the operation performed in a fold on small quantities at a time.

720. The late lambing ewes are separated from the ewes and lambs at the end of the lambing season, and kept by themselves, that they may be more under the eye of the shepherd, than if scattered over all the farms, where they are exposed to the risk of not growing as fat as they would have done had they come to be nearly equal to the rest of the flock when weaned; or if they are too late for this, that they may get ready for the butcher by the month of August, beyond which period the ewes must be much injured by networking them. (Supp. § 5, art. Agr. 178.)

728. Milking, in dock-farming, is performed when the wool has risen sufficiently, which is easily known by the appearance of a new growth. The barren sheep are first brought to the washing pool. Sometimes they are hand-washed by men who stand in the pool, and have the sheep forced towards them singly; but generally, the Cheviot sheep, especially in the southern parts of the country, is kept in a body for three or four times successively; and it is desirable that they should have room to swim a little, and come out on a green low bank on the opposite side. After being washed, the sheep are preserved as far as possible from rubbing against earthen dykes or banks, and from lying down on any dirt or earth, or muck, in the washing pool. (Supp. § 5.)

730. Marking, as in general sheep-farming (718.), takes place before the sheep are turned out to pasture; they are marked, commonly with the owner's initials, by a stamp, or brand in provincial language, which is cut in this fluid state; and it is not usual to place this mark on different parts of the body, according to the sheep's age.

733. The weaning of lambs takes place when they are about three months old, sometimes sooner. When the ewes are gathered to be washed or shorn, the ewe lambs are kept for supplying the place of the ewes that are washed or shorn, and occasionally sold. In the spring, a few sheep are kept in the season's grass, and a few for a week or two in the folds, and in the winter, in a fold or pen, about six to eight weeks. In the mean time the ewe hogs, or gimmers, as they are denominated after shearing, have joined the ewe stock, and the lambs, when brought home, go to the pasture which they had occupied. Wherever they may be kept in winter, it is always desirable to allow them a few turnspits, along with a full feed of coarse herbage.

734. The practice of milking ewes after the separation of the lambs is still continued in a few places. This very objectionable management is generally continued for six or eight weeks. The value of the milk of each ewe for this time may not exceed from one shilling and sixpence to two shillings. In the late lambing season, it is kept with the same care for some as long as two or three weeks. The cream is separated from the ewe milk, and made into butter for smearing, and the milk itself mixed with cow milk, and converted into cheese. The most skilful store-masters, however, have either laid aside milking, unless for a few days, or if have shortened the interval between milking, to keep them on a full feed of butter and hay, by which means they are kept fattened, and fatten more quickly than those kept on a dry diet, and are ready for the market sooner.

735. The selection of the crones or old ewes to be sold generally takes place in September or October, when she are sold to the feeder, and replaced by lambs of the current year. On the lower hills, ewes are generally disposed of after having lambed three seasons, or under four and a half years of age. In some situations they are kept till a far older age; and when they are disposed of after another year on lower grounds, it is commonly for the interest of the store-farmer to sell them when still in their full vigour. Skilful managers do not content themselves with drafting them merely according to age; for there is no disadvantage in keeping a few of the best another year, they take this opportunity of getting rid of such of the flock of other ages as are not of good shapes, or are otherwise objectionable. As soon as the ewes are disposed of as drawn from the flock, they are kept by themselves on better pasture, if the circumstances of the farm will admit of it. Sometimes they are carried on till they are fattened, and turned out for the winters in the same manner as the other sheep kept on a stock farm. The most common materials are butter and tar, mixed in different proportions; a greater proportion of tar being employed for the hogs or young sheep than for the older ones. The proportions are also different on almost every farm, and more tar is thought to be necessary, according to their general situation and exposure. In Roxburghshire, some mix tar with thirty-six pints of butter; but for the larger number it is more common to allot only one stone (twenty-four pounds) of butter to two gallons of tar. (Roxburghshire Report, p. 155.) A common proportion of late has been about fourteen pounds of butter to two Scotch pints of tar (nearly 3 quartz Eaths) for aewe, and fourteen and ten pounds, and in this mixture they should smear from twenty to twenty-five of each, which is the number one man can do in a day. The expense, according to present prices, will be about nine-pence for each sheep: other articles, such as oil, paper, and twine, which have been recommended in place of butter; but none of them are in general use, and the only addition that is necessary if it is a little butter, or some other oil, is added to the mixture, and applied upon the tar, and the mixture is constantly stirred till it becomes cool enough for use. The wood is accurately parted into rows from the head to the tail of the animal, and the salve is carefully spread upon the skin in such a manner that it is not allowed to lie upon the bottom of each cart, when the sheep is loaded. The salve of salving has undergone a change within these four years, and is not so general now as formerly, the low price of smeared wool having forced the store-masters to try other ingredients than tar. In the Farmer's Magazine, xxv. are some notices of those experiments on salving; which have not, however, been so long in use as to afford certain results. The object appears to be to keep the wool as dry as possible to dispense with tar, by which the wool is rendered unfit for certain sorts of manufacture.
